[snip]
```

Next, we examine LISP multicast. Only static RP is supported, and only PIM-SSM and PIM-ASM are supported for transport. CSR2 is the RP and also has an ASM receiver on group 225.1.1.1. CSR9 has an SSM receiver on group 232.1.1.1 from source 10.1.10.1 (CSR1). CSR1 is just a test host and has no interesting configuration. CSR2 and CSR9 have identical configurations except for the IGMP group joined. CSR2 requests ASM while CSR9 requests SSM from CSR1 explicitly. CSR10 just enables PIM on the LISP and LAN interfaces, along with the basic RP/SSM information.

```
! CSR2 and CSR9
interface Loopback1
 ip pim sparse-mode

interface LISP1.101
 ip pim sparse-mode

ip pim vrf C1 rp-address 10.2.2.2
ip pim vrf C1 ssm default

! CSR9 only
interface Loopback1
 ip igmp join-225.1.1.1

! CSR9 only
interface Loopback1
 ip igmp join-group 232.1.1.1 source 10.1.10.1

! CSR10
interface GigabitEthernet2.510
 ip pim sparse-mode

interface LISP1.101
 ip pim sparse-mode

ip pim vrf C1 rp-address 10.2.2.2
ip pim vrf C1 ssm default
```

Examining SSM first, we see that CSR9 has the (S,G) configured on its loopback and sends the (S,G) PIM join towards CSR10. The RPF interface on CSR9's (S,G) entry specifies that it should arrive via the LISP1.101 interface, with 101 representing the IID.

```
! CSR9
PIM(1): Insert (10.1.10.1,232.1.1.1) join in nbr 10.7.10.10's queue
PIM(1): Building Join/Prune packet for nbr 10.7.10.10
PIM(1): Adding v2 (10.1.10.1/32, 232.1.1.1), S-bit Join
PIM(1): Send v2 join/prune to 10.7.10.10 (LISP1.101)
```

```
CSR9#show ip mroute vrf C1 232.1.1.1 10.1.10.1 | begin \
(10.1.10.1, 232.1.1.1), 4d05h/stopped, flags: sLTI
Incoming interface: LISP1.101, RPF nbr 10.7.10.10
Outgoing interface list:
Loopback1, Forward/Sparse, 4d05h/00:00:49
```

The packet travels from CSR9's RLOC to CSR10's RLOC as a LISP unicast packet (yellow addresses, cyan port number). This means that CSR10 and CSR9 already mapped one another's EID prefixes to RLOCs for multicast to work. I'm not going to dig into all the details of the packet, but below is a PIM packet (protocol 0x67, 103, green) inside of LISP that contains 232.1.1.1 and 10.1.10.1 (pink) within the packet. I will assume this is the (S,G) join. LISP is intelligent enough to know the unicast RLOC destination for PIM joins based on the RPF interface. All we had to do was configure PIM on the LISP virtual interface, which makes LISP multicast very easy.

```
CSR7#show monitor capture CAP buffer dump

0070: 04200A01 0A01
```

CSR10 receives the packet, performs the ETR functions to decapsulate it, and then processes the PIM join. CSR10 directs traffic out towards the LISP process using EID-to-RLOC mappings found inside IID 101. Because the PIM neighbor address is included with the OIL line entry, we know that the LISP virtual interface is operating in PIM NBMA mode despite it not being explicitly configured. This makes sense because, like DMVPN, LISP is treating each neighbor as a separate unicast peer.

```
! CSR10
PIM(3): Received v2 Join/Prune on LISP1.101 from 10.9.9.9, to us
PIM(3): Join-list: (10.1.10.1/32, 232.1.1.1), S-bit set
```

```
PIM(3): Update LISP1.101/10.7.9.9 to (10.1.10.1, 232.1.1.1), Forward state,
by PIM SG Join
```

All possible debugging has been turned off

```
CSR10#show ip mroute vrf C1 232.1.1.1 10.1.10.1 | begin \((
(10.1.10.1, 232.1.1.1), 4d05h/00:03:19, flags: sT
Incoming interface: GigabitEthernet2.510, RPF nbr 0.0.0.0
Outgoing interface list:
LISP1.101, 10.7.9.9, Forward/Sparse, 1d04h/00:03:19
```

When CSR1 starts sending multicast EID traffic, CSR10 encapsulates it inside unicast LISP packets and sends it towards the receiver, CSR9. We can see traffic being sent by looking at counters on both CSR9 and CSR10. A quick EPC verification outbound on CSR7 confirms this. The outer encapsulation has a UDP (0x11, protocol 17, green) header and sends traffic from 10.7.10.10 to 10.7.9.9 (yellow) using port 4341 (0x10F5, cyan) in RLOC space. The inner packet is ICMP (0x01, protocol 1, green) from 10.1.10.1 to 232.1.1.1 (yellow) in EID space. Like most tunneling techniques, LISP transports multicast inside unicast, which is inefficient.

```
CSR9#show ip mroute vrf C1 232.1.1.1 10.1.10.1 count | begin ^Group
Group: 232.1.1.1, Source count: 1, Packets forwarded: 17, Packets received:

[snip]
```

Last, we will examine ASM over LISP. CSR2 is both the RP and the receiver, so the (*,G) join doesn't transit the list network. CSR10 should send a register message to CSR2 when it receives traffic from CSR1; this message will have LISP and PIM encapsulation. Because this is an ordinary unicast packet, we won't capture it on EPC. Upon receipt, CSR2 generates an (S,G) join back towards the newly-discovered source.

```
! CSR10
PIM(3): Check RP 10.2.2.2 into the (*, 225.1.1.1) entry
```

PIM(3): Adding register encap tunnel (Tunnel0) as forwarding interface of (10.1.10.1, 225.1.1.1).

! CSR2

PIM(2): Received v2 Register on LISP1.101 from 10.1.10.10
for 10.1.10.1, group 225.1.1.1

PIM(2): Adding register decap tunnel (Tunnel1) as accepting interface of (10.1.10.1, 225.1.1.1).

PIM(2): Insert (10.1.10.1,225.1.1.1) join in nbr 10.7.10.10's queue

PIM(2): Building Join/Prune packet for nbr 10.7.10.10

PIM(2): Adding v2 (10.1.10.1/32, 225.1.1.1), S-bit Join

PIM(2): Send v2 join/prune to 10.7.10.10 (LISP1.101)

When CSR10 receives traffic down the shared tree, it sends a (*,G) prune to the RP for CSR1 as the specific source. It also receives the (S,G) join from CSR9 and updates it MRIB entry.

! CSR10

PIM(3): Building Triggered (*,G) Join / (S,G,RP-bit) Prune message for 225.1.1.1

PIM(3): Join-list: (10.1.10.1/32, 225.1.1.1), S-bit set

PIM(3): Add LISP1.101/10.2.8.2 to (10.1.10.1, 225.1.1.1), Forward state, by PIM SG Join

CSR10 continues to register the group until told to stop by the RP. Once the registration process is complete and the (S,G) tree is built, the PIM control-plane converges and native multicast flows without issue. The multicast traffic is still unicast-encapsulated via LISP (unicast), so it introduces transport inefficiencies. The PIM ASM source discovery and tree construction process is identical here as it is in a non-LISP network.

! CSR2

PIM(2): Received v2 Register on LISP1.101 from 10.1.10.10
for 10.1.10.1, group 225.1.1.1

PIM(2): Removing register decap tunnel (Tunnel1) as accepting interface of (10.1.10.1, 225.1.1.1).

PIM(2): Installing LISP1.101 as accepting interface for (10.1.10.1, 225.1.1.1).

PIM(2): Insert (10.1.10.1,225.1.1.1) join in nbr 10.7.10.10's queue

PIM(2): Building Join/Prune packet for nbr 10.7.10.10

PIM(2): Adding v2 (10.1.10.1/32, 225.1.1.1), S-bit Join

PIM(2): Send v2 join/prune to 10.7.10.10 (LISP1.101)

PIM(2): Send v2 Register-Stop to 10.1.10.10 for 10.1.10.1, group 225.1.1.1

! CSR10

PIM(3): Received v2 Register-Stop on LISP1.101 from 10.2.2.2

PIM(3): for source 10.1.10.1, group 225.1.1.1

PIM(3): Removing register encap tunnel (Tunnel0) as forwarding interface of (10.1.10.1, 225.1.1.1).

PIM(3): Clear Registering flag to 10.2.2.2 for (10.1.10.1/32, 225.1.1.1)

Quickly checking the MRIB counters on both routers confirms proper multicast operation.

```

35. Describe, implement, and troubleshoot GRE and mGRE-based VPN

35.1 P2P GRE tunneling and GRE features

GRE is a commonly used mechanism of tunneling various layer 3 protocols over IPv4 or IPv6. It is more flexible than IP-in-IP or IPv6-in-IP tunnels and can carry pretty much anything (IPv4, IPv6, IPX, CLNS, AppleTalk, etc). The basics of GRE configuration are not covered here, but the GRE header has many additional options which are worth evaluating. The current architecture is built on a hub-and-spoke architecture. CSR4 and XRV13 are hubs and CSR10, CSR9, and CSR2 are spokes. The hubs have individual P2P GRE tunnels to all spokes. Spoke to spoke traffic is routed through the hubs in this design. The collection of P2P tunnels means that we can test different features on different tunnels.

The relevant configurations are shown below on the hubs only. These are basic tunnels that require no explanation. The SP core MPLS L3VPN configuration, along with the customer IGP (OSPF) over tunnels, is not shown. These features are verified in detail later.

```
! XRV13
interface tunnel-ip113
  description P2P GRE XRV13 TO CSR10
  ipv4 unnumbered Loopback0
  tunnel source 10.11.13.13
  tunnel destination 10.7.10.10

interface tunnel-ip213
  description P2P GRE XRV13 TO CSR2
  ipv4 address 10.2.13.13 255.255.255.0
  tunnel source 10.11.13.13
  tunnel destination 10.8.2.2

interface tunnel-ip413
  description P2P GRE XRV13 TO CSR4
```

```
ipv4 address 10.4.13.13 255.255.255.0
tunnel source 10.11.13.13
tunnel destination 10.4.12.4
```

```
! CSR4
interface Tunnel24
description P2P GRE CSR4 TO CSR2
ip address 10.2.4.4 255.255.255.0
tunnel source 10.4.12.4
tunnel destination 10.8.2.2
```

```
interface Tunnel49
description P2P GRE CSR4 TO CSR9
ip address 10.4.9.4 255.255.255.0
tunnel source 10.4.12.4
tunnel destination 10.7.9.9
```

From a network perspective, each router has a default route towards the tunnel endpoints. This is the best match they have. For example, building CSR9's tunnel to CSR4 requires underlay connectivity to CSR4's tunnel source. This is ultimately achieved through the default route. Designs like this are valid since the private WAN traffic (OSPF routes) are routed through the tunnel, but all other "Internet" traffic is routed natively to the SP. This means that when routers need to reach CSR5, the Internet router, the traffic is never GRE-encapsulated. If the Internet access points aren't through the corporate WAN hub, this design is very efficient.

```
CSR9#show ip cef 10.4.12.4 detail

```

Before looking at GRE features, we examine some basic techniques often used on GRE tunnels. IP unnumbered is often used on P2P links to conserve IP addressing since it is very rare that traffic is destined to these transit links. The tunnel between XRv13 and CSR10 shows this. The OSPF database's

point-to-point entry shows the interface number as being the router interface address. A common misconception is that the last octet of the “Link Data” comes from the SNMP ifmib; it is actually the software interface descriptor block (IDB). The output below illustrates this clearly, although it isn’t terribly relevant.

```
CSR10#show ip ospf 1 0 database router self-originate
```

```
OSPF Router with ID (10.10.10.10) (Process ID 1)
```

```
Router Link States (Area 0)
```

```
LS age: 29
Options: (No TOS-capability, DC)

Advertising Router: 10.10.10.10
LS Seq Number: 80000006
Checksum: 0x1E48
Length: 60
Area Border Router
Number of Links: 3
```

```
Link connected to: another Router (point-to-point)
```

```
(Link ID) Neighboring Router ID: 13.13.13.13
```

```
(Link Data) Router Interface address: 0.0.0.24
```

```
Number of MTID metrics: 0
```

```
TOS 0 Metrics: 1000
```

```
[snip]
```

```
CSR10#show ifnum list | include Tu113
```

```
HWIDB    15      ACTIVE    Tu113          20000000 00000000 00000000
00060000 00000000 00000000 00000071 00000000
SWIDB    24      ACTIVE    Tu113          28000000 00000000 00000000
00060000 00000000 00000000 00000071 00000000
```

```
CSR10#show snmp mib ifmib ifindex Tunnel113
```

```
Interface = Tunnel113, Ifindex = 16
```

We see similar output on XRv13. This router is a hub so it has many more P2P tunnels than CSR10 (7 versus 3). I have not found a command to display the XRv IDB information, but I assume it works similarly on all Cisco platforms. The number 25 is likely allocated by this IDB process.

```
RP/0/0/CPU0:XRv13#show ospf 1 0 database router self-originate
```

```

[snip]

Another approach specific to IS-IS and OSPF is to strip the IP routing component for that subnet from the link-state information. IS-IS does this by explicitly advertising only passive interface IP prefixes in its LSPs. OSPF removes the stub link-state information from its LSA-1 to achieve the same effect. XRv3 only appears to support OSPFv2 prefix-suppression for secondary addresses, so we will demonstrate this on XE routers. The tunnel between CSR4 and CSR2 is removed from the LSA-1, so no one will have an OSPF-learned route for 10.2.4.0/24.

```
! CSR2 and CSR4
interface Tunnel24
 ip ospf prefix-suppression
```

Looking at CSR10, it has no route for this prefix and when examining the LSA-1s from CSR2 and CSR4, the prefix is not listed as a stub network. CSR2 and CSR4 still have connected routes, of course, which is necessary for route recursion. This feature should be mutually exclusive with IP unnumbered; unnumbered links have no stub network to suppress in the first place. The output is long so we can be thorough in verifying that the stub networks were properly suppressed. Even outside of GRE, this feature is valuable on any transit links where there are no end hosts.

```

Tunnels can also exist in different VRFs than their endpoints. This allows a tunnel to have a front-door VRF (FVRF) for its endpoints but still run IGP in the global table. CSR2 uses this technique; this is a great way to ensure there are no tunnel recursion errors as the tunnel endpoints and the tunnel itself are in different VRFs. Be sure to update the underlay routing to be VRF-aware; in this case, we update the static route towards the tunnel endpoint.

```

! CSR2
vrf definition FVRF
  address-family ipv4

interface Tunnel24
  tunnel vrf FVRF

ip route vrf FVRF 10.0.0.0 255.0.0.0 10.8.2.8

```

We can verify this using a simple show command as seen below.

```

CSR2#show ip interface tunnel24 | include VRF
Tunnel VPN Routing/Forwarding "FVRF"

```

The smallest GRE header, not counting the IP encapsulation component, is 4 bytes long. The first 4 bits can tell how long the header will be; 1 of the bits is unused, but the other 3 represent additional 4-byte features. For example, if 2 of the bits are set, the GRE header will be 12 bytes long (original 4 plus 8 more). The header also carries the protocol type (like an ethertype) along with the version. This allows GRE to carry multiple protocols. As an example, the tunnel between CSR2 and XRv3 has IPv6 enabled with LL addressing (not shown). Capturing inbound on CSR8, we see IPv4 packets with GRE-type 0800 and IPv6 packets with GRE-type 0x86DD. The IPv4 packet happens to be an OSPFv2 hello and the IPv6 packet is IPv6-ICMP, but that is beyond the scope of this test. The first 16 bits (4 hex digits) are all zero, indicating no special GRE extensions are in use. Simply being able to carry a protocol type in the GRE header is what gives GRE its flexibility.

```

GRE has many interesting features beyond basic tunneling. First, we will examine the GRE tunnel key. This is a 32-bit unsigned integer that differentiates tunnels with the same source and destination, and is commonly used in networks with many overlays and a single underlay. It is also a form of weak security used to prevent against misconfigurations or from accepting stray packets. To make it easy to see this in

the packet capture, we will use the decimal key 3203386110 (0xBEEFCAFE) on the tunnel between CSR2 and XRv13.

```
! CSR2
interface Tunnel213
 tunnel key 3203386110

! XRv13
interface tunnel-ip213
 tunnel key 3203386110
```

If the tunnel keys do not match, "debug tunnel keepalive" will reveal the fault. To test it, I temporarily change one of the keys to 11111 (not shown) to ensure the key is being checked.

```
! CSR2
Tunnel: Drop, Failed to find tunnel for GRE/IPv4 packet 10.11.13.13->10.8.2.2
(tbl=4, "FVRF" len=104, ttl=252)
```

After capturing on CSR8, we can see the packet is 4 bytes larger (122 to 126) and contains our new 4-byte key. The original 4 byte header is shown in yellow with the new GRE tunnel key in green. The beginning of the header changed also; the first hex digit is 0010 in binary, and the 1 represents the flag indicating that the tunnel key is present.

0030:	0050AB62	00000159	162A0A02	0D02E000	.P.b...Y.*.....

Next, we enable the GRE checksum feature. This is a 16-bit field, where the low-order 16-bits are always set to 0. This used for validating the packet for corruption. This is not supported on XR, but can be enabled unidirectionally.

```
! CSR2
interface Tunnel213
 tunnel checksum
```

Notice that packet has grown by another 4 bytes to 130. The checksum is 0xCE10 and the next 16 bits are set to 0 (cyan). The GRE key follows that. Notice the very first hex digit of the GRE header is 0xA, which is 1010. We conclude that the leftmost bit represents the checksum option. Note: The rightmost

bit represents the sequence numbers field. GRE sequence numbers, the third GRE option, do not appear to be supported on XE or XR, so they are not tested.

```

```

Although not a header extension, GRE can also issue regular keepalives. This is supported on P2P tunnels only, but it's essentially an empty GRE packet. We enable this on the CSR2-XRv13 tunnel using the basic "keepalive" command.

```
! CSR2
interface Tunnel213
 keepalive 3 9

! XRv13
interface tunnel-ip213
 keepalive 3 9
```

Keepalives can be enabled unidirectionally since it works like BFD echo-mode. Inside the GRE packet from CSR2 to XRv13, there is another GRE packet which has the source/destination headers reversed. This allows XRv13 to respond normally. Notice the GRE header at the very end of the packet. The protocol number is 0x0000 and the reserved field that was previously 0x0000 is now 0x0001. I assume this low-level detail signals a keepalive to the GRE process, although technically it is part of the sequence number field. The debug below also shows the keepalive being sent and received, but notice the direction is represented by the inner packet (from the destination to the source). I used the same colors as above to show the GRE basic header (yellow), checksum (cyan), and key (green). I use grey to show the inner GRE packet with reversed IP addresses.

```
CSR8#show monitor capture CAP buffer dump

0040: 0D0D0A08 0202A000 0000D60F 0001BEEF .....
0050: CAFE
```

```
Tunnel213: sending keepalive, 10.11.13.13->10.8.2.2 (len=32 ttl=255),
counter=1
Tunnel213: keepalive received, 10.11.13.13->10.8.2.2 (len=32 ttl=251),
resetting counterund all
```

When we enable it on XRv13, there does not appear to be a debug that shows the keepalives. However, outbound EPC on CSR8 reveals those packets. Notice that XRv13 is not using checksums, which explains the different in length (74 versus 82, account for two checksums).

```

```

You can see a quick summary of the GRE special features using the command below.

```
CSR2#show interfaces tunnel213 | section GRE|Keepalive
Description: P2P GRE CSR2 TO XRv13
Keepalive set (3 sec), retries 9
Tunnel protocol/transport GRE/IP
Key 0xBEEFCAFE, sequencing disabled
Checksumming of packets enabled

RP/0/0/CPU0:XRv13#show interfaces tunnel-ip213 | include is enabled
Keepalive is enabled, interval 3 seconds, maximum retry 9
Key is enabled, key value 3203386110
```

The tunnel TOS and TTL parameters are straightforward and self-explanatory. These set the TOS and TTL of the outer IP header only. We demonstrate this on CSR9 sending traffic to CSR4 and capturing inbound on CSR7. CSR9 will set the outer IP header TOS to DSCP CS3 rather than reflect the tunneled value. The tunnels default TTL is 255 but we can shorten the “length” of the tunnel by selecting a smaller value.

```
! CSR9
interface Tunnel49
 tunnel tos 96
 tunnel ttl 8
```

The OSPF hellos have DSCP CS6 set, but the tunnel overrides it to DSCP CS3. The tunnel TTL has been reduced to 8 for additional security. Comparing it to the packets going to XRv3 (a different and unmodified tunnel), the differences become clear. The TTLs are highlighted in yellow and the TOS values in green. Failing to specify a tunnel TOS means that the value is copied from the inner IP header; the packets going to XRv3 have DSCP CS6 which was copied from the OSPFv2 hellos inside. Failing to specify a TTL means that a value of 255 is always used.

IP PROTOCOL: 1
[snip]
```

The tunnel bandwidth feature is another command on a GRE tunnel of limited value. I believe it is informational only and is meant to be used for Layer1 transports that don't have the same bandwidth in both directions, like satellite links using Rate-Based Satellite Control Protocol (RBSCP) tunnels. I assume this information is communicated to upper-layer protocols as it is not a policer for the tunnel. The default is 8000 kbps and this value also doesn't seem to affect IGP cost calculation. This feature is probably not relevant for GRE tunnels at all, but we will investigate it briefly.

```
CSR9#show interfaces tunnel913 | include bandwidth
Tunnel transmit bandwidth 8000 (kbps)
Tunnel receive bandwidth 8000 (kbps)

CSR9#show ip ospf interface brief | include Tu913
Tu913      1      0      10.9.13.9/24      1000      P2P      1/1
```

We modify the tunnel on CSR9 going to XRv3 to be TX 4 Mbps and RX 1 Mbps. There is no change in the IGP metric.

```
! CSR9
interface Tunnel913
 tunnel bandwidth transmit 4096
 tunnel bandwidth receive 1024

CSR9#show interfaces tunnel913 | include bandwidth
Tunnel transmit bandwidth 4096 (kbps)
Tunnel receive bandwidth 1024 (kbps)

CSR9#show ip ospf interface brief | include Tu913
Tu913      1      0      10.9.13.9/24      1000      P2P      1/1
```

Only the traditional "bandwidth" command has an effect on the IGP metric. There is also a "bandwidth receive" command. Having 4 different bandwidth commands on a single interface can be very confusing. I've set the bandwidth to 16 Mbps and the RX BW to 2048, making all 4 values are different.

```
! CSR9
interface Tunnel913
 bandwidth 16384
 bandwidth receive 2048
```

The 16 Mbps value is used for the OSPF cost calculation now. The "tunnel bandwidth receive" is deprecated according to Cisco documentation as this was once used for RBSCP. RBSCP is beyond the scope of this document, but only the "transmit" command is used now.

```
CSR9#show interfaces tunnel 913 | include bandwidth|BW
MTU 9976 bytes, BW 16384 Kbit/sec, RxBW 2048 Kbit/sec, DLY 50000 usec,
Tunnel transmit bandwidth 4096 (kbps)
Tunnel receive bandwidth 1024 (kbps)
```

```
CSR9#show ip ospf interface brief | include Tu913
Tu913      1      0      10.9.13.9/24      6      P2P      1/1
```

Tunnel entropy uses a hash value for the lower-order 8 bits of the tunnel key to introduce more randomness into the packet header. It is a 6-tuple combining src/dst IP, src/dst port, VRF, and IP protocol. The goal of this is better load sharing assuming routers in the core do their ECMP-hash-based forwarding using the tunnel key. This also means the GRE key must be 24 bits or less, so using 0xBEEFCAFE again won't work. We will enable this on the CSR2-CSR4 tunnel, and we must enable entropy before adding the key.

```
CSR2(config-if)#tunnel key ?
<0-4294967295> key
```

When entropy is enabled, the key can only be 24 bits. Using a small key 0xBEEF (48879) will work. We configure this on both ends of the tunnel then verify it was successful. Both ends must have a matching key with the entropy option enabled. To enable entropy, you must configure entropy first and then the tunnel key; order of operations is significant.

```
! CSR2 and CSR4
interface Tunnel24
 tunnel entropy
 tunnel key 48879
```

```
CSR2(config-if)#tunnel key ?
<0-16777215> key
```

```
CSR2#show interfaces tunnel24 | include Key
Key 0xBEEF, sequencing disabled
Tunnel Entropy Calculation Enabled (24-bit Key)
```

```
CSR4#show interfaces tunnel24 | include Key
Key 0xBEEF, sequencing disabled
Tunnel Entropy Calculation Enabled (24-bit Key)
```

Looking into the packet by capturing outbound on CSR8, we can see the lower-order 8 bits of the key are no longer part of the "key" used for security purposes between the endpoints. The top flow is a telnet session and has entry entropy value 0xBE, and the bottom flow is an ICMP flow with entropy value 0x7C. The protocol numbers 6 and 1 for TCP and ICMP, respectively, are highlighted in pink. Because every flow is likely to have a different GRE key (256 total combinations), if the underlying architecture can do hashing based on the GRE key rather than the src/dst IP information, better load sharing can be achieved. I cannot find an authoritative source that tells me whether XE/XR routers can do load sharing based on the GRE tunnel key, nor can I find a mechanism to configure it. The concept is very clever and could be very useful for load sharing in an IP-based core network.

Additional Reading – Reference configurations "gre-p2p"

35.2 Dynamic Multipoint VPN (DMVPN) basics

DMVPN isn't really an SP technology but is very commonly used in enterprise networks to connect branch sites to corporate HQ sites in hub-spoke fashion using multipoint GRE (mGRE) tunnel interfaces. Since mGRE is within the blueprint, we examine DMVPN also; understanding what enterprise customers are doing over the SP network is valuable for customer interactions and joint troubleshooting. Encryption via IPSec can optionally be added, but this is beyond the scope of the SP blueprint. Spokes register to the hubs using Next Hop Resolution Protocol (NHRP) so that hubs can dynamically discover hubs, which simplifies provisioning for new spokes. The registration message contains a mapping between the VPN addresses (the typically-private tunnel IP) and the NBMA addresses (the typically-public address, AKA the tunnel endpoints). The process is somewhat similar to LISP where ETRs register EID-to-RLOC mappings to the MS. In most deployments the hubs dynamically create downstream multicast mappings based on spoke registrations. DMVPN comes in three variations:

1. **Phase 1:** Still takes advantage of mGRE tunnels, but does not provide any direct spoke-to-spoke communication. All spoke-to-spoke traffic is hair-pinned through the hub. In single-hub deployments, spokes can use a P2P GRE tunnel construct with some additional configuration for simplicity. In dual-hub deployments, spokes can use the mGRE tunnel construct similar to the hubs. Phase 1 is really only recommended for small, single-hub deployments with little to no spoke-to-spoke traffic.

2. **Phase 2:** Uses mGRE tunnel interfaces everywhere as it provides dynamic spoke-to-spoke tunnel creation. When a spoke needs to reach a remote spoke, it queries the hub requesting the NBMA (underlay) address for a given VPN (overlay) address. The hub resolves the remote spoke's NBMA address (processed detailed later) and the local spoke can directly encapsulate traffic with a GRE destination of the remote spoke's NBMA address. So long as the underlay is intelligently designed to provide spoke-to-spoke access (such as the Internet or SP WAN links), this technology works well.

3. **Phase 3:** Similar to phase 2 but it enhances scalability. Using new NHRP redirect messages from the hub and CEF shortcuts on the spokes, a hierarchical hub architecture can be designed to further regionalize the network. All of the routers still share a tunnel mesh (and thus an IP subnet), but the IGP neighbor discovery process can be bounded by the hub hierarchy. It also allows the hub routers to advertise very coarse aggregate routes, like defaults, and not provide more specific matches. This is not possible in Phase 2 since the spokes still need to know the actual VPN next-hops for every destination, even other spokes.

The diagram below shows a network logically similar to the P2P GRE architecture. The main difference from the P2P GRE setup is that XRv3 is no longer a "hub" since it does not support DMVPN at all. It will be the "Internet" router and CSR5 will be a hub, alongside CSR4. CSR10, CSR9, and CSR2 remain spokes. This lab does not detail advanced DMVPN designs with respect to IGP, multicast, etc. The focus is on basic DMVPN constructs, detailed debugging, and control-plane verification.

General restrictions:

- GRE keepalives only work on tunnels that have explicit destinations configured. Even on mGRE spokes with NHRP static mappings, GRE keepalives are not sent. Recall that keepalives can be configured unidirectionally, so a Phase 1 spoke in a single-hub deployment, for example, can use GRE keepalives to probe the hub for reachability.

- Multicast NBMA designs apply. For Phase 1, both PIM (*,G) and (S,G) joins can be enabled since the next-hop for all routes is the hub. For Phase 2, only PIM (*,G) joins are valid since the RPF neighbor will appear spoke-to-spoke (directly connected), which is not supported for LL multicast. There are no PIM neighbors laterally across any flavor of DMVPN. For Phase 3, (S,G) joins can work, but only if the NHO process is in effect. NHRP (H) routes are used for RPF and break multicast when they exist. These H routes are common when performing summarization on spokes.

35.2.1 Phase 1

In this setup, CSR4/CSR5 are DMVPN phase 1 hubs. CSR9 and CSR10 use mGRE interfaces as spokes to connect to both hubs. They use static mappings towards each hub for unicast and multicast. CSR2 demonstrates using a P2P tunnel to CSR4, which would be common in a single-hub deployment. To

connect to CSR5, both CSR2 and CSR5 must provision a new, separate P2P GRE tunnel since CSR2 cannot use the same subnet on multiple interfaces in the same VRF. For phase 1, this doesn't affect forwarding, but complicates the design. The OSPF network type should be P2MP on the hubs and either P2MP or P2P on the spokes depending on the design.

  ip ospf network point-to-point
```

```

ip ospf 1 area 0
keepalive 3 3
tunnel source 10.8.2.2
tunnel destination 10.4.12.4
tunnel vrf FVRF

```

We will watch the NHRP registration process in detail from the perspective of a spoke (CSR9) and a hub (CSR5). The debugs are verbose so I have stripped out the unnecessary parts. First, CSR9's tunnel comes up and adds the static mappings to the NHRP cache. Technically, those static mappings count as NHRP entries also. The NHRP process iterates over the configured hub mappings in series. I also show the NHRP cache at present to show the mappings were added. The command used is "debug nhrp".

```

! CSR9
NHRP: if up: Tunnel100 proto 'NHRP_IPv4'

```

Next, CSR9 will attempt to register its VPN/NBMA mappings to each NHS in series. Priority values can determine whether NHS' are more preferred than others (0 is the highest priority) according to Cisco documentation, but this is used in specific HA architectures. NHRP "clusters" can be used for failover scenarios; these features are not examined in great detail here. Below, the debugs from CSR9 show the registration packets being sent, and the replies being received from each NHS. The transition from 'E' to 'RE' means that the NHS entry went from "expecting replies" to "expecting replies and receiving them". This means registration was successful and each NHS is marked as "up".

```

4 (00:16:55 ago)

```

Viewing the process from the hub's perspective, we see the registration requests come in from the spoke NBMA addresses. Inside that message are the VPN/NBMA mappings, and this allows the hub to create a dynamic NHRP entry for both multicast and unicast traffic. The hub sends the registration reply so the spoke knows its request was processed.

```

Because NHRP is a component of DMVPN, we can also use the DMVPN-derived debugging. These provide significant additional detail over the NHRP debugs. The same process is shown again, and I've focused on the actual NHRP registration packet. The details of the registration packet are displayed using this debug, so checking for authentication mismatches or NAT-traversal issues (with IPSec) is simplified. The command used is "debug dmvpn all nhrp". The new F, M, and C fields represent several new concepts. "F" is the fixed field, specifying address-family, version, and type. "M" is the mandatory information field, primarily used by the hub to construct dynamic mappings to spokes that register. "C" is the client information element (CIE) field that can be added as NHS speakers need to communicate information back and forth. These three fields are shown in green just for identification purposes. CSR9 sends a registration request to CSR5, and CSR5 responds with a registration reply.

Below is an example of mismatched NHRP authentication. The NHS doesn't actually send a message back to say the authentication failed, but it fails to send a registration response. CSR9 continues to retransmit the message, which could hint at an authentication issue. Before continuing, we correct the authentication issue. This test was simply to show that the debug can help debug those issues.

```

We have also configured IPv6 in the overlay also. DMVPN can be an IPv6 transition strategy to connect separated IPv6 islands. The NHRP syntax is nearly identical for IPv6 as it is for IPv4 and is shown below;

only the additional components for IPv6 are shown. Some commands require netmask specification, unlike IPv4. EIGRP is used for IPv6 unicast routing. There are two significant configurations for EIGRP. Disabling split-horizon on the hubs, which are NBMA interfaces, is important to distribute updates to spokes. Making the spokes EIGRP stubs is a good design practice which prevents them from being transit routers and ensures they can never receive EIGRP queries for active prefixes.

```
! Generic hub (CSR5)
interface Tunnel100
  ipv6 address FE80::5 link-local
  ipv6 address 2001:10:0:100::5/64
  ipv6 nhrp authentication NHRPAUTH
  ipv6 nhrp map multicast dynamic
  ipv6 nhrp network-id 100

router eigrp VPN
  address-family ipv6 unicast autonomous-system 65000
    af-interface Tunnel100
      no split-horizon

! Generic spoke (CSR9)
interface Tunnel100
  ipv6 address FE80::9 link-local
  ipv6 address 2001:10:0:100::9/64
  ipv6 nhrp authentication NHRPAUTH
  ipv6 nhrp map 2001:10:0:100::4/128 10.4.12.4
  ipv6 nhrp map 2001:10:0:100::5/128 10.5.6.5
  ipv6 nhrp map multicast 10.4.12.4
  ipv6 nhrp map multicast 10.5.6.5
  ipv6 nhrp network-id 100
  ipv6 nhrp nhs 2001:10:0:100::4 priority 5
  ipv6 nhrp nhs 2001:10:0:100::5 priority 2
```

In cases where routers are behind the "stub", like CSR1 and XRv4, you can either leak routes through or summarize on the stub router. CSR10 uses the leak method while CSR9 uses the summary method. CSR2 only advertises connected routes as it has nothing to summarize nor any downstream EIGRP neighbors. This is a quick side-note and is not directly related to DMVPN, but general EIGRP design over NBMA architectures. These same concepts apply to IPv4 as well.

```
! CSR10
ipv6 prefix-list PL_IPV6_ALL seq 5 permit ::/0 le 128

route-map RM_EIGRP_LEAK_IPV6 permit 10
  match ipv6 address prefix-list PL_IPV6_ALL

router eigrp VPN
  address-family ipv6 unicast autonomous-system 65000
    eigrp stub connected leak-map RM_EIGRP_LEAK_IPV6
```

```

! CSR9
router eigrp VPN
 address-family ipv6 unicast autonomous-system 65000
   eigrp stub connected summary
 af-interface Tunnel100
   summary-address ::14:14:14:0/112
 af-interface GigabitEthernet2.594
   summary-address ::/0

```

```

! CSR2
router eigrp VPN
 address-family ipv6 unicast autonomous-system 65000
   eigrp stub connected

```

The debugs for NHRP are identical between IPv4 and IPv6. CSR9 includes its public IPv6 address in the "M" stanza and its LL address in the first "C" stanza.

```

```

CSR9 receives the reply, accepts it, and programs it to its NHRP cache. It creates two entries, one for CSR5's real VPN address, and one for its LL address, as both are mapped to the same IPv4 NBMA address. The LL address has a special NHRP flag to identify it as such. It is interesting to note that the "type" of the LL mapping is static, although it was learned. Since it is bound to a hub that was a static mapping, the two are considered equivalent enough to share these attributes.

```

! CSR9
NHRP: Receive Registration Reply via Tunnel100 vrf 0, packet size: 228
(F) afn: AF_IP(1), type: IPv6(86DD), hop: 255, ver: 1
    shtl: 4(NSAP), sstl: 0(NSAP)

    src protocol: 2001:10:0:100::9, dst protocol: 2001:10:0:100::5
[snip, same as above]

```

```

CSR9#show ipv6 nhrp 2001:10:0:100::5/128
2001:10:0:100::5/128 via 2001:10:0:100::5
  Tunnel100 created 00:10:22, never expire
  Type: static, Flags: used
  NBMA address: 10.5.6.5

```

```

CSR9#show ipv6 nhrp FE80::5/128
FE80::5/128 via FE80::5
  Tunnel100 created 00:10:28, never expire
  Type: static, Flags: nhs-ll
  NBMA address: 10.5.6.5

```

At this point, the IPv6 capability in the second hub at CSR4 has not been configured yet. Below is an example of output that indicates one fully functional hub, and one dysfunctional one. The NHS at CSR4, from CSR9's perspective, is expecting replies but not receiving them; 6 requests were sent but 0 received.

```

CSR9#show ipv6 nhrp nhs detail

```

Legend: E=Expecting replies, R=Responding, W=Waiting

Tunnel100:

2001:10:0:100::4 E priority = 5 cluster = 0 req-sent 6 req-failed 0
repl-recv 0

2001:10:0:100::5 RE priority = 2 cluster = 0 req-sent 1 req-failed 0
repl-recv 1 (00:00:45 ago)

Pending Registration Requests:

Registration Request: Reqid 85, Ret 32 NHS 2001:10:0:100::4 expired (Tu100)

Quickly adding the IPv6 NHRP hub configuration to CSR4 (similar to CSR5 and not shown), we can see the registration is successful on CSR9. Also notice that CSR5 has a better (lower) priority than CSR4, which should come into play with phases 2 and 3.

CSR9#show ipv6 nhrp nhs detail

Legend: E=Expecting replies, R=Responding, W=Waiting

Tunnel100:

2001:10:0:100::4 RE priority = 5 cluster = 0 req-sent 42 req-failed 0
repl-recv 1 (00:00:13 ago)

2001:10:0:100::5 RE priority = 2 cluster = 0 req-sent 1 req-failed 0
repl-recv 1 (00:34:37 ago)

Another way to quickly verify that all spokes have registered is by checking the IPv6 NHRP caches on the hub in brief form. CSR4 has 3 spokes while CSR5 only has two; recall that CSR2 is only in the DMVPN connected to CSR4, using a P2P tunnel for connectivity to CSR5. The hubs show the spoke LL addresses as dynamic mappings as they were contained inside the NHRP registration requests initially.

CSR5#show ipv6 nhrp brief

The only time phase 1 NHRP resolution requests are issued by spokes is when they are trying to directly reach one another's VPN addresses when the route recursion points to a connected route. This also only occurs when there are multiple hubs and the spokes use mGRE interfaces (not P2P interfaces). For example, CSR9 tries to ping CSR10's VPN address along with its loopback. In IPv4, this VPN address is an OSPF /32 route given the P2MP network type used. The loopback is a normal OSPF /32 route. Both of these follow the regular routing rules through the hub, and there are no reachability issues. This is a very rare case, but the process is near-identical for other DMVPN phases, so we analyze it here.

```
CSR9#show ip cef 10.0.100.10
10.0.100.10/32
  nexthop 10.0.100.4 Tunnel100
  nexthop 10.0.100.5 Tunnel100
```

```
CSR9#show ip cef 10.10.10.10
10.10.10.10/32
  nexthop 10.0.100.4 Tunnel100
  nexthop 10.0.100.5 Tunnel100
```

```
CSR9#ping 10.0.100.10
Type escape sequence to abort.
Sending 5, 100-byte ICMP Echos to 10.0.100.10, timeout is 2 seconds:
!!!!
Success rate is 100 percent (5/5), round-trip min/avg/max = 29/34/42 ms
```

```
CSR9#ping 10.10.10.10
Type escape sequence to abort.
Sending 5, 100-byte ICMP Echos to 10.10.10.10, timeout is 2 seconds:
!!!!
Success rate is 100 percent (5/5), round-trip min/avg/max = 16/33/46 ms
```

Doing the same test to CSR2's VPN address and loopback is different. The path to the loopback is a normal OSPF /32 route, but the path to the VPN endpoint is the connected /24 route. Because of the NBMA network, CSR9 does not have direct connectivity to this. It needs to query the hub for resolution.

```
CSR9#show ip cef 10.0.100.2
10.0.100.0/24
  attached to Tunnel100
```

```
CSR9#show ip cef 2.2.2.2
2.2.2.2/32
  nexthop 10.0.100.4 Tunnel100
  nexthop 10.0.100.5 Tunnel100
```

When it queries the hub, only CSR4 can respond since CSR2 is not running DMVPN with CSR5 at all (uses P2P tunnel). The resolution request is shown below. This is CSR9 asking CSR4 "What is the NBMA address for VPN address 10.0.100.2"? I usually look at the "M" field first since it contains 3 of the 4 key pieces of information, and the resolution request seeks to find the fourth.

```
! CSR9
NHRP: Send Resolution Request via Tunnel100 vrf 0, packet size: 88
src: 10.0.100.9, dst: 10.0.100.2
(F) afn: AF_IP(1), type: IP(800), hop: 255, ver: 1
    shtl: 4(NSAP), sstl: 0(NSAP)
    pktsz: 88 extoff: 52
(M) flags: "router auth src-stable nat ", reqid: 8
    src NBMA: 10.7.9.9
    src protocol: 10.0.100.9, dst protocol: 10.0.100.2
(C-1) code: no error(0)
    prefix: 32, mtu: 9976, hd_time: 7200
    addr_len: 0(NSAP), subaddr_len: 0(NSAP), proto_len: 0, pref: 0
```

The hub receives the resolution request, performs a route lookup, and then forwards the request towards CSR2. This is similar to what a LISP MR/MS does when receiving map-requests from ITRs. The NHS inserts a "transit NHS record extension" into the packet which includes its local VPN/NBMA mapping. This simply means that an NHS was in the resolution transit path from source to destination (the path of the resolution request). Although technically CSR4 knows the NBMA mapping for 10.0.100.2, it forwards the request to CSR2 for authoritative resolution.

```
! CSR4
NHRP: Receive Resolution Request via Tunnel100 vrf 0, packet size: 88

```

CSR2 receives that modified resolution request from CSR9 (via CSR4 in the middle), performs a route lookup. CSR2 determines it's a local route and generates a resolution reply for CSR9, using the NHS as transit.

```

! CSR2
NHRP: Receive Resolution Request via Tunnel100 vrf 0, packet size: 108
(F) afn: AF_IP(1), type: IP(800), hop: 254, ver: 1

NHRP: Route lookup for destination 10.0.100.2 in (0x0) yielded interface
Tunnel100, prefixlen
NHRP: Request was to us. Process the NHRP Resolution Request.

```

At this point, CSR2 has enough information to where it can add CSR9's NBMA address to its local cache. Unlike LISP, the entire resolution process does not have to happen in both directions. CSR2 marks this entry as "implicit" because an explicit resolution was not triggered; it was able to glean the information from a resolution request to which it was responding.

```
! CSR2
NHRP: Tunnel100: Cache update for target 10.0.100.9/32 next-hop 10.0.100.9
10.7.9.9

CSR2#show ip nhrp 10.0.100.9
10.0.100.9/32 via 10.0.100.9
Tunnel100 created 00:18:03, expire 01:58:31
Type: dynamic, Flags: router implicit nhop
NBMA address: 10.7.9.9
```

The first line of the debug below is interesting and details why Tunnel25 was not used for NHRP signaling; it is not part of the DMVPN network and should not be used for NHRP-resolved routes. CSR2 adds a new extension for "responder address", which makes sense since CSR2 originated the resolution reply. This is where the NBMA mapping is encoded and ultimately how CSR9's initial question is answered. Notice this information is in the first CIE field also.

```
! CSR2
NHRP: Pak out Tunnel25 would leave logical NBMA network
NHRP: Attempting to send packet via NHS 10.0.100.4
NHRP: Send Resolution Reply via Tunnel100 vrf 0, packet size: 136
src: 10.0.100.2, dst: 10.0.100.4
(F) afn: AF_IP(1), type: IP(800), hop: 255, ver: 1

```

CSR9 receives this packet which is full of information. The original 'M' stanza contains three out of the four key pieces of information: source VPN, source NBMA, and destination VPN. This was originated by CSR9 in the first place. The entire purpose of this entire process was to resolve the destination NBMA to reach CSR2. The following stanza (CIE) contains the "answer" to that query, which is 10.8.2.2 mapped to VPN address 10.0.100.2. The remaining fields are used internally by NHRP for tracking from which NHS this resolution was proxied, among other things.

```

! CSR9
NHRP: Receive Resolution Reply via Tunnel100 vrf 0, packet size: 156
(F) afn: AF_IP(1), type: IP(800), hop: 254, ver: 1
    shtl: 4(NSAP), sstl: 0(NSAP)
    pktsz: 156 extoff: 60
(M) flags: "router auth dst-stable unique src-stable nat ", reqid: 8
    src NBMA: 10.7.9.9
    src protocol: 10.0.100.9, dst protocol: 10.0.100.2
(C-1) code: no error(0)
    prefix: 32, mtu: 9976, hd_time: 7200
    addr_len: 4(NSAP), subaddr_len: 0(NSAP), proto_len: 4, pref: 0
    client NBMA: 10.8.2.2
    client protocol: 10.0.100.2
Responder Address Extension(3):
(C) code: no error(0)
    prefix: 32, mtu: 9976, hd_time: 7200
    addr_len: 4(NSAP), subaddr_len: 0(NSAP), proto_len: 4, pref: 0
    client NBMA: 10.8.2.2

```

```
CSR9#show ip nhrp 10.0.100.2
10.0.100.2/32 via 10.0.100.2
      Tunnel100 created 00:00:33, expire 01:59:26
      Type: dynamic, Flags: router nhop
      NBMA address: 10.8.2.2
```

This is a very bad design because CSR2 is only a P2P tunnel, it can never install dynamic NHRP mappings on that interface as the destination is fixed. CSR9 can send traffic to 10.0.100.2, but the reply traffic will never work. In this way, phase 1 can be tricky to troubleshoot and understand. Even though the NHRP mappings appear correct, there is no connectivity between VPN addresses. Normally, you would have a single hub with all sites using P2P tunnels (with prefix-suppression of sorts, somewhat like CSR2), or multiple hubs plus all sites using mGRE (CSR9 and CSR10).

Next, we can begin data-plane testing; most reachability is achievable both within the VPN and to the Internet site, with the exception of some VPN addresses due to an intentionally poor design described above. Only connected networks (transit links) have Internet access, since NAT is not configured as it is beyond the scope of this test. Of greater interest is determining the routing path; a traceroute on CSR9 to CSR10 clearly shows the hub(s) in the transit path. The CEF table confirms this both for CSR10's loopback and the OSPF summary behind it. This is the main disadvantage of DMVPN phase 1 and the reason why it's rarely used.

```
CSR9#traceroute 10.10.10.10
Type escape sequence to abort.
Tracing the route to 10.10.10.10
VRF info: (vrf in name/id, vrf out name/id)
 1 10.0.100.4 17 msec
   10.0.100.5 25 msec
   10.0.100.4  8 msec
 2 10.0.100.10 33 msec *  64 msec
```

```
CSR9#show ip cef 10.10.10.10
10.10.10.10/32
  nexthop 10.0.100.4 Tunnel100
  nexthop 10.0.100.5 Tunnel100
```

```
CSR9#show ip cef 1.1.1.1
1.1.1.0/24
  nexthop 10.0.100.4 Tunnel100
  nexthop 10.0.100.5 Tunnel100
```

The same is true for IPv6 routing. Because of EIGRP stub routing, The hubs cannot reach one another without a P2P tunnel or static mappings on their mGRE interfaces. I add a P2P tunnel quickly to achieve reachability (not shown). CSR9's paths to other remote sites are shown also, and as expected, route through the hubs directly.

```
CSR5#show ipv6 cef ::4:4:4:4
::4:4:4:4/128
  nexthop FE80::4 Tunnel145
```

```
CSR9#show ipv6 cef ::1:1:1:1
::1:1:1:1/128

  nexthop FE80::5 Tunnel100
```

```
CSR9#show ipv6 cef ::2:2:2:2
::2:2:2:2/128
  nexthop FE80::4 Tunnel100
  nexthop FE80::5 Tunnel100
```

Additional Reading – Reference configurations "dmvpn1"

35.2.2 Phase 2

DMVPN phase 2 solves some of the problems associated with phase 1 by allowing spokes to send traffic directly to one another. This implies that all routers must have the same mGRE interface (no P2P links with static tunnel destinations) so that they can install NHRP mappings to remote NBMA addresses inside the same DMVPN. GRE keepalives are not supported at any node, hub or spoke, in this design. From a routing perspective, EIGRP must be configured with split-horizon disabled (like phase 1) and with next-hop-self disabled (specific to phase 2). This allows spoke VPN addresses for re-advertised routes to be maintained, which allows traffic to traverse the dynamic spoke-to-spoke tunnels. For OSPF, a multi-access network type should be used (broadcast or nonbroadcast). Typically broadcast is used as it simplifies the configuration, but the spokes must have their DR priorities set to 0 as only hub nodes have connectivity to all endpoints to distribute OSPF updates. We will use OSPFv2 for IPv4 and EIGRP for IPv6 as we did in phase 1. I have removed the P2P tunnel between CSR4/CSR5 and used a static mapping on CSR5 to build the linkage. CSR5 is a backup hub that references CSR4 as an NHS also, so within a local DMVPN phase 2 design, you can achieve a little bit of hierarchy this way. For brevity, only the relevant

configuration components are shown, since the basic configuration (addresses, tunnel source, etc) has not changed.

```

Before starting, a quick check of NHRP registrations on the hubs is valuable to ensure the network has converged. Notice that CSR4 has all dynamic entries, where CSR5 has a static entry for CSR4. Then, checking OSPF neighbors confirms that LL multicast is functioning (assuming "broadcast" network type) and IGP can converge. The hubs should be candidate DRs while the spokes are forced to never be DRs (DROthers).

When CSR1 sends traffic to XRv14, CSR10 is the next router in the path. However, CSR10 does not know the NBMA address for 10.0.100.9, which is the next-hop of the route for 14.14.14.0/24. CSR10 also does not report having an NHRP mapping for this VPN address (IGP next-hop), which is loosely analogous to not having an ARP entry (MAC address) for a next-hop IP address.

```
CSR1#show ip cef 14.14.14.14
0.0.0.0/0
  nexthop 10.1.10.10 GigabitEthernet2.510
```

```
CSR10#show ip cef 14.14.14.14
14.14.14.0/24
  nexthop 10.0.100.9 Tunnel100
```

```
CSR10#show ip nhrp 10.0.100.9
[no output]
```

The lack of a valid NHRP mapping for 10.0.100.9 triggers an NHRP resolution request on CSR10. CSR10 sends this request to CSR4 only, presumably before it comes first in the configuration as the priorities are the same. The debug below is very chatty (I've reduced many parts), but it effectively says "I don't know the NBMA for 10.0.100.9, so I will ask CSR4. I have the NBMA/VPN mappings for the NHS, so I will send a resolution request for 10.0.100.9 to the NHS NBMA address".

```

```

CSR4 receives the resolution request from CSR10 attempting to resolve the NBMA address for CSR9. CSR4 does a route lookup for 10.0.100.9 and sees that it points out of Tunnel100, which means it's within the same DMVPN. Like a standard NHRP resolution, the NHS adds itself as the "forward transit NHS" inside the request before sending the traffic towards the destination.

```

CSR9 receives the resolution request originated by CSR10 and forwarded by CSR4. CSR9 performs a route lookup for the destination and sees that it is a local interface, so the packet is processed locally. CSR9 also knows the NBMA/VPN mappings for the source, CSR10, as this information is contained in the original request. This is considered an "implicit" mapping and is valid for entry into CSR10's NHRP cache.

```

```

Unlike the process we examined for phase 1, the resolution reply is sent directly back to CSR10, which means the NHS won't see it again. I presume this is because the IGP routing directs the traffic directly back to the spoke; with Phase 1, the hub was always in the transit path, even with the NHRP resolutions that occurred between VPN addresses. As expected, CSR9 adds the "responder address extension" field to the NHRP message so that the originator knows who responded.

```

```

The output below shows the entry that CSR9 adds upon receiving the resolution request from CSR10. Since the source NBMA was contained in the message, an "implicit" entry can be added since it's fair to assume that the return traffic should be sent towards the source NBMA address. After all, CSR9 just used this mapping to send a resolution reply directly back to CSR9, avoiding the transit NHS on the return path.

```

CSR9#show ip nhrp 10.0.100.10
10.0.100.10/32 via 10.0.100.10
    Tunnel100 created 00:36:11, expire 01:23:48
    Type: dynamic, Flags: router implicit used nhop
    NBMA address: 10.7.10.10

```

CSR10 receives the resolution reply from CSR9 which contains its NBMA address 10.7.9.9. CSR10 adds this to its NHRP cache and can directly encapsulate unicast traffic to this spoke inside mGRE. The debug reveals this new NBMA information in several different ways, which is why I have trimmed it down.

```

```

Below is the final result of the NHRP process. CSR10 adds this NBMA entry as a dynamic entry into its NHRP cache. Nothing changes in the RIB/FIB since the next-hop for the routes behind a spoke is the spoke's VPN address. As long as NHRP can provide the dynamic "tunnel destination", we can use traceroute to prove traffic routes directly between nodes; notice CSR4/CSR5 are not in the transit path.

```

CSR10#show ip nhrp 10.0.100.9
10.0.100.9/32 via 10.0.100.9
  Tunnel100 created 00:35:53, expire 01:24:06
  Type: dynamic, Flags: router nhop
  NBMA address: 10.7.9.9

```

```

CSR1#traceroute 14.14.14.14 source 1.1.1.1
Type escape sequence to abort.
Tracing the route to 14.14.14.14
VRF info: (vrf in name/id, vrf out name/id)
 1 10.1.10.10 0 msec 0 msec 1 msec
 2 10.0.100.9 1 msec 1 msec 5 msec

```

```
3 10.9.14.14 8 msec * 2 msec
```

We will quickly test IPv6 also without much debugging. The nature of EIGRP provides two identical routes to CSR10 for ::14:14:14:0/112 since the hubs are leaving the LL next-hop the same and simply re-advertising it (like a route-reflector). CSR10 does not have an NHRP mapping for this LL next-hop, which is essentially a VPN address for CSR9.

```
CSR1#show ipv6 cef ::14:14:14:14
::14:14:14:0/112
  nexthop FE80::10 GigabitEthernet2.510
```

```
CSR10#show ipv6 cef ::14:14:14:12
::14:14:14:0/112
  nexthop FE80::9 Tunnel100
  nexthop FE80::9 Tunnel100
```

```
CSR10#show ipv6 nhrp FE80::9/128
[no output]
```

When CSR1 sends traffic, the NHRP process takes place. CSR9 sends its request to CSR4 (small debug shown), which forwards it to CSR10. CSR10 then responds directly.

```
! CSR9
NHRP: NHRP successfully mapped '2001:10:0:100::4' to NBMA 10.4.12.4
NHRP: IPv6-resolution: Sending packet to NHS 2001:10:0:100::4/10.4.12.4 on
Tunnel100 - status: 1
```

When CSR9 receives the resolution reply, it installs the LL mapping into the NHRP cache. Even though it learns the publicly-routable VPN address of CSR9 via the "responder address extension", this is not relevant for routing in this case.

```
! CSR9

Additional Reading – Reference configurations "dmvpn2"

35.2.3 Phase 3

DMVPN phase 3 achieves greater scalability than both phases 1 and 2, as mentioned briefly earlier. In phase 2, spokes still need the routes from every other spoke since the VPN next-hops must be preserved. Even if each node can summarize its back-end networks into a single summary, this could still mean thousands of routes in a large enterprise deployment with thousands of spokes. With phase 3, the hubs can originate default routes, which directs all traffic to them initially. Using new NHRP redirect messages (like ICMP redirects), the hubs can redirect follow-on packets to spokes directly. Spokes can install CEF shortcuts for one another's NBMA addresses to provide spoke-to-spoke connectivity. Hubs can also be stacked hierarchically to regionalize the DMVPN architecture, which is not examined here. The configuration requires one new command on hubs and one new command on spokes. Also, EIGRP still needs split-horizon disabled but the next-hops should be changed to be the hub (next-hop-self). To demonstrate the scalability improvements, as well as new NHRP route types, we will originate coarse aggregate routes from the hubs (2001::/16). The reason for using these is so that the enterprise WAN traffic (2001::/16) is kept inside the DMVPN, while default traffic (::/0) goes to the SP without encapsulation via existing default routes. OSPF P2MP network type should be used to allow the next-hops to be the hubs. This makes the phase 3 configuration a hybrid between phase 1 and phase 2 with respect to NHRP and IGP configurations.

The link-state nature of OSPF makes hub summarization impossible, so each spoke still has OSPF routes for each remote spoke since they share a common area. For this reason (and others), OSPF is generally a poor choice of IGP over DMVPN. For IPv6 routes learned via EIGRP, every spoke only has a pair of 2001::/16 routes towards the hubs. My original IPv6 addressing plan was poor in that the remote networks (loopbacks) did not summarize well; they have been updated to reflect good EIGRP design using the format 2001:x:x:x:x/128 (not shown). In this way, each spoke will have a very small number of routes regardless of how many spokes are added to the network.

```

```

We will send traffic from CSR1's to CSR2's loopback using IPv4. Unlike phase 2, CSR10 does have a valid IP route for 2.2.2.2/32 via CSR4 and CSR5, implying that CSR10 does not send a resolution request to the NHS. To determine which coarse aggregate it uses for the initial packet, we check the FIB. CSR10 will encapsulate this packet and send it to CSR5 according to the output below. Including the "virtual" keyword will show the tunnel interface information (VPN address) in addition to the tunnel destination (NBMA address).

```
CSR10#show ip cef exact-route virtual 1.1.1.1 2.2.2.2
1.1.1.1 -> 2.2.2.2 => IP midchain out of Tunnel100, addr 10.0.100.5
7FE069004A78 => IP adj out of GigabitEthernet2.570, addr 10.7.10.7
```

When CSR5 receives this packet, it routes it normally out of the tunnel (hair-pin) and tells CSR10 "I will forward this packet, but you should send traffic straight to CSR2 in the future". This is what the NHRP

redirect message does. Although the message type is “Traffic Indication”, the code identified in the mandatory (M) field is “redirect”. Notice that it does not contain CSR2's NBMA address anywhere in the packet; this is just an indication for CSR10 to originate a traditional NHRP resolution request to resolve CSR2's NBMA. This packet goes from CSR5 directly back towards 1.1.1.1/32, where CSR10 is the DMVPN endpoint servicing that host.

```

```

CSR10 receives the traffic indication message (redirect) and attempts to resolve the NBMA mapping for 2.2.2.2. Unlike phase 2, phase 3 resolves NBMA/VPN mappings where the VPN address is the final destination, not the actual VPN address/next-hop. A poorly summarized network could result in a huge NHRP cache in this case; the reason the VPN address itself is not resolved is because the hub summarization has hidden the NBMA topology. The NBMA topology and IGP routing are totally decoupled with DMVPN phase 3, which allows it to scale (assuming IGP summarizes well). The resolution request contains the usual three parameters: source NBMA, source VPN, and destination VPN (final destination, in this case). This is sent towards CSR5, which is the NHS that originated the redirect.

```

CSR5 receives the resolution request, performs a route lookup, and forwards it back out of the tunnel towards CSR2. CSR5 inserts the "forward transit NHS record" into the packet so CSR2 knows which NHS forwarded the message. As an NHS, CSR5 knows the NBMA address of CSR2, which is 10.8.2.2. This is the first time we have seen that address in any debug message. As expected, the NHS does not respond with this directly to CSR10, but forwards the request towards the final destination, 2.2.2.2/32.

CSR2 receives the resolution request from CSR10 via the NHS CSR5. Although the packet isn't directed at the VPN address, CSR2 acknowledges that it is the "egress" router so it processes, and replies to, the received request. Inside the "responder address" field, CSR2 returns its NBMA address, which is the fundamental problem NHRP is meant to solve. Although CSR2 does know the NBMA address of CSR10 (the source), it sends its resolution reply to the NHS on the way back. I presume that the reason the NHS is used on the way back is because the route back to the "source protocol" isn't "connected" anymore, so NHS does not make assumptions about its whereabouts (even though it technically could, given the source NBMA address).

```

```

CSR10 receives the resolution reply, processes it, and adds an NHRP mapping for 2.2.2.2/32 to the NHRP cache. NHRP tries to add a new NHRP route to the RIB with AD 250 for 2.2.2.2/32. Since there is already an exact-match OSPF route with AD 110, the next-hop-override (NHO) process is triggered instead. This is a function of the CEF shortcut; we know the VPN next-hop for 2.2.2.2/32 is 10.0.100.2, so rather than use the hubs as the IGP next-hops, the router overwrites them. Ultimately, the FIB is augmented by the NHRP cache in this way. The routing table displays these entries with "%" symbols. The VPN address of CSR2 is also marked as an "nhop" and the final destination is not, which is self-explanatory.

```

Unlike phase 2, there isn't an "implicit" NHRP entry on the remote side router. Even though CSR2 showed adding the tunnel endpoints from the original request, the redirect process still occurs. The entire process occurs again in the opposite direction so that CSR2 knows how to reach 1.1.1.1/32. Most of the debugs are not shown again, but there is one significant difference. On CSR10, the route 2.2.2.2/32 could not be added to the RIB because the OSPF route (AD 110) was better than the NHRP route (AD 250). Since CSR2 never had a route for the exact prefix 1.1.1.1/32, it is able to add this longer match. CSR2 only had a summary for 1.1.1.0/24, which was enough for routing to work, but means the NHO process need not occur. The NHRP entry does not specify "nho" for the 1.1.1.1/32 entry, but does for the VPN address of CSR10, which is expected. New NHRP routes are denoted by "H" in the routing table.

```

The process for IPv6 is identical. Because phase 3 makes no assumptions about the VPN topology, having coarse aggregates pointing to the hub will always work. Before sending any traffic from CSR1 to CSR2, CSR10 only has aggregates for 2001::/16. This kind of summarization means that NHO will be non-existent for real destinations since there is never an exact-match route already known by the spokes. Before sending any traffic between spokes, CSR10 only has the hub-generated aggregate routes.

```

CSR10#show ipv6 cef 2001:2:2:2::2
2001::/16
    nexthop FE80::4 Tunnel100
    nexthop FE80::5 Tunnel100

```

When CSR10 receives IPv6 traffic from CSR1 towards CSR2, it initially sends the traffic along the regular routing path because it knows the NBMA address for both NHS', per the RIB and static NHRP mappings. Upon receipt, the hub returns the NHRP redirect message towards the sender, forwards the original packet back out of the tunnel, and expects to receive NHRP resolution from the sender soon. Because the process happens in both directions (no "implicit" mappings), the NHS tracks the redirects for a short time until they expire. After expiration, they can be regenerated if the spoke resolution requests fail for whatever reason. Below shows pending redirects from both CSR10 and CSR2 with 6 seconds left until they expire.

```

CSR4#show ipv6 nhrp redirect

```

I/F	NBMA address	Destination	Drop Count	Expiry
Tunnel100	10.7.10.10	2001:2:2:2::2	1	00:00:06
Tunnel100	10.8.2.2	2001:1:1:1::1	1	00:00:06

Upon receipt of the redirect message, CSR10 begins the usual phase 3 resolution process. In short, the process is as follows: CSR10 sends traffic to hub, hub sends redirect to CSR10, and then CSR10 issues a resolution request to follow the normal NHRP process. For these resolutions, the NHRP resolution reply does not transit the NHS and is sent directly back from the target spoke to the originating spoke. I speculate that this is different from the previous example because with OSPF P2MP, the routers had an OSPF /32 to each VPN endpoint where with EIGRPv6 they did not. Having the NHRP route (not an IGP route) to the VPN endpoint may enable DMVPN to bypass the NHS on the reverse path when sending the replies.

[no output]

```

When the resolution completes, CSR10 has specific CEF entries for CSR2's loopback, which was the target address inside the VPN. The following outputs mirror the IPv4 outputs seen earlier for other tests. The "rib" flag signifies that there are exact-match routes for these entries in the RIB, but they don't necessarily have to be H-routes. If "rib" is present and "nho" is absent, the route is surely an H route. When both are present, the route is a non-H route; NHO and H-routes are mutually exclusive within the context of a single prefix.

```

CSR10#show ipv6 cef 2001:2:2:2::2
2001:2:2:2::2/128
    nexthop 2001:10:0:100::2 Tunnel100

Additional Reading – Reference configurations "dmvpn3"

35.3 mGRE-based L3VPN

The L3VPN-over-mGRE feature is used to dynamically connect customers within remote provider sites together. Imagine a CSC-like scenario where the core carrier refuses to provide a labeled-unicast service across two customer carrier islands. The connectivity between the customer carriers is IP only, which means MPLS transport doesn't work automatically. The L3VPNNoGRE feature fully automates the tunnel endpoint discovery and maintains the BGP VPNv4/v6 allocated labels between customer carrier sites. The feature also supports the MVPN profile 0 (PIM/GRE) implementation for efficient multicast transport; this is sensible since profile 0 works well over CSC architectures. The network used for this test is quite complex; it is a CSC scenario where the core carrier provides an IP-only VPN to three customer carrier sites. The core carrier uses mLDP to transport LSM for variety since the core and customer carriers can use entirely different MVPN techniques. The customer carrier sites must use profile 0 since their CSC service is IP only. CSR6, CSR9, and CSR10 are the customer PE routers that service the true customers, CSR1, CSR4, and CSR8. The XrV routers don't support the dynamic L3VPNNoGRE feature, and are P routers within the customer carriers. Different IGP's are used in different regions for variety. Before continuing with this test, ensure you understand MVPN/CSC technologies and techniques.

The configuration is rather involved, so the initial verifications are limited to basic reachability. Within the core, CSR2 is the RR for VPNv4/v6 AFs using the BGP listen command (dynamic peer groups). We quickly verify that the neighbors are up and we receive at least some routes. VPNv6 in the core carrier was a test for other things and is not directly related to this test.

```

```

```
BGP peergroup IBGP listen range group members:
0.0.0.0/0
```

Total dynamically created neighbors: 3/(100 max), Subnet ranges: 1

We also check the BGP RR for the customer carrier, which is CSR6. Rather than check the BGP summary for the neighbors, I will check the BGP tables for VPNv4, VPNv6, and IPv4 MDT. We learn the remote two VPNv4/v6 routes (one from each remote PE), as well as the MDT sources for MVPN transport within the IPv4 MDT AFI.

```

Given this, we know the BGP control plane is properly built and there is IP reachability between CSR6, CSR9, and CSR10. If there were not, the BGP sessions between customer carrier PEs would not work. The LSP tracing verification procedure does not work, because there is no LSP between these PEs, despite them trying to run VPNv4/v6. We receive a BGP label from the remote PE (CSR10), but we have no transport label. XRv2 and XRv4 do not allocate labels because 10.10.10.10/32 was a BGP learned prefix from their perspective, and the provider never allocated a label for it via labeled-unicast.

```

```

The solution for this problem involves creating an L3VPN encapsulation profile. Here, we specify tunnel template parameters, somewhat similar to auto-tunnel configuration in TE. We can specify the tunnel protocol (only IPv4/GRE is currently supported) along with optional tunnel source and key. We then create a generalized route-map for both VPNv4 and VPNv6 that changes the next-hop on ingress. The logic is that when BGP receives a VPNv4/v6 prefix, it looks at the next-hop and creates a GRE tunnel endpoint from it. This alleviates the need for DMVPN-style signaling and allows spokes to communicate directly without extra signaling. BGP already knows all the endpoints since these are also the VPNv4/v6 next-hops. Even though only IPv4 is supported for the outer encapsulation at this time, VPNv6 via 6VPE can function using this feature, so we also adjust the IPv6 next-hop.

```
! CSR6, CSR9, CSR10
l3vpn encapsulation ip L3VPN_PROFILE
  transport ipv4 source Loopback0
  protocol gre key 65000

route-map RM_VPN_NHOP_IN permit 10
  set ip next-hop encapsulate l3vpn L3VPN_PROFILE
  set ipv6 next-hop encapsulate l3vpn L3VPN_PROFILE

router bgp 65000
  address-family vpnv4 unicast
    neighbor IBGP route-map RM_VPN_NHOP_IN in
  address-family vpnv6 unicast
    neighbor IBGP route-map RM_VPN_NHOP_IN in
```

After applying this configuration to the customer carrier PEs, the BGP path now shows reachability to 10.10.10.10 via Tunnel0. This is a dynamic entity that serves as a template, and the tunnel configuration reflects the configured source address and key. Nothing has changed with the MPLS label bindings.

```

CSR6#show bgp vpnv4 unicast vrf VPN 192.168.4.0/24
BGP routing table entry for 65000:6:192.168.4.0/24, version 10
Paths: (1 available, best #1, table VPN)
  Not advertised to any peer
  Refresh Epoch 2
  Local, (Received from a RR-client), imported path from
65000:10:192.168.4.0/24 (global)
    10.10.10.10 (metric 10) (via default) (via Tunnel0) from 10.10.10.10
(10.10.10.10)
      Origin incomplete, metric 0, localpref 100, valid, internal, best
      Extended Community: RT:65000:10
      Connector Attribute: count=1
        type 1 len 12 value 65000:10:10.10.10.10
        mpls labels in/out nlabel/10006
      rx pathid: 0, tx pathid: 0x0

```

```

CSR6#show derived-config interface tunnel0
Building configuration...

```

```

Derived configuration : 151 bytes

```

```

!
interface Tunnel0
  ip unnumbered Loopback0
  no ip redirects
  ipv6 enable
  tunnel source Loopback0
  tunnel mode gre multipoint
  tunnel key 65000
end

```

The routing table never changed, but now VPN traffic destined for those BGP next-hops is sent inside this tunnel using the L3VPN encapsulation profile. There is a new adjacency in the FIB that details these connections. One is listed as IP and one is listed as MPLS.

```

CSR6#show adjacency 10.10.10.10
Protocol Interface Address
IP Tunnel0 10.10.10.10 (4)
TAG Tunnel0 10.10.10.10 (4)

```

Digging into the encapsulation details, we see the only difference between these two entries is the protocol type (0x0800 for IP versus 0x8847 for MPLS). We expect the MPLS traffic inside this tunnel to have the VPN label directly beneath this layer of encapsulation, before the customer IP header. The tunnel key of 65000 (0xFDE8) marks the end of the GRE encapsulation. Immediately following this tunnel key, assuming the type is 0x8847, will be the customer VPN label.

```

CSR6#show adjacency 10.10.10.10 encapsulation

```

```

```

We can also check the tunnel endpoints to see what was discovered. Because this tunnel is used for VPNv4 and VPNv6, both IPv4 and IPv6 BGP next-hops are bound to that transport address.

```

CSR6#show tunnel endpoints tunnel 0
Tunnel0 running in multi-GRE/IP mode

```

As an example, we will send traffic from CSR4 to CSR8 inside the customer network. The IGP cost between CSR7 and CSR5 in the core carrier is high cost, so capturing on CSR2's interface towards CSR7 should yield the most encapsulation. The significant components are highlighted in different colors and are shown below.

```
CSR4#ping 192.168.8.8
```

```
CSR2#show monitor capture CAP7 buffer dump
0000: 000C295C E1E9000C 29664C2C 81000DC7  ..)\....)fL,....

0050: 7B3B000A 00010000 00009568 6D9BABCD  {;.....hm...
[snip]
```

The first 12 bytes are the destination and source MAC addresses, respectively. The next 4 bytes specify 802.1Q encapsulation with VLAN ID 0xDC7 (3527). 0x8847 specifies MPLS unicast, and 0x7D8 (2008) is the LDP label from CSR2 to reach CSR5, highlighted in yellow.

```
CSR7#show mpls ldp bindings 5.5.5.5 32
lib entry: 5.5.5.5/32, rev 8
  local binding:  label: 7000
  remote binding: lsr: 5.5.5.5:0, label: imp-null
  remote binding: lsr: 2.2.2.2:0, label: 2008
```

The next label is 0x13B9 (5049) which is the VPNv4 label from CSR5 describing reachability to CSR9. The S-bit is set, as expected. This is the bottom-most label and is also highlighted in yellow.

```
CSR7#show bgp vpnv4 unicast vrf CH labels
Network          Next Hop          In label/Out label
Route Distinguisher: 33:7 (CH)
  6.6.6.6/32      3.3.3.3           nolabel/3001
                  2.2.2.2           nolabel/2003
  9.9.9.9/32      5.5.5.5           nolabel/5049
  10.10.10.10/32  10.255.11.11      7010/nolabel
```

Next is an IP packet with protocol 0x2F (47) for GRE in cyan. Source and destination addresses are highlighted in green (10.10.10.10 -> 9.9.9.9). The payload of this GRE/IP packet is 0x8847 with a tunnel key of 0xFDE8 (65000). The next label is 0x232D (9005) which is the VPN label allocated by CSR9 describing reachability to the connected route with CSR8, highlighted in grey. This proves that the VPN label immediately follows the GRE header.

```
CSR10#show bgp vpnv4 unicast vrf VPN labels

192.168.1.0	6.6.6.6	nolabel/6002
192.168.4.0	0.0.0.0	10006/nolabel (VPN)
192.168.8.0	9.9.9.9	nolabel/9005

The final significant piece of this encapsulation is the final IP header, which is IP protocol 1 (ICMP), from 192.168.4.10 to 192.168.8.9 (in pink). This is the original VPN traffic. We can summarize the encapsulation for unicast traffic as follows:

1. Layer 2 encapsulation – Ethernet, FR, ATM, PPP, etc
2. MPLS transport core labels – LDP, RSVP-TE, TE-FRR, Segment Routing, etc
3. MPLS VPN core label – BGP VPNv4 always, since only IPv4 is supported for outer encapsulation
4. IP/GRE header (L3VPN encap profile) – 4 or 8 bytes depending on key, type is always 0x8847
5. MPLS VPN customer label – BGP VPNv4 or VPNv6 between customer PEs
6. Customer traffic – IPv4 or IPv6 customer traffic

Next, we will examine multicast transport. Both the customer carrier and final customers are using SSM only to simplify testing, so there are no RPs anywhere. The core carrier is PIM-free using mLDP with CSR3 as the root of the MP2MP tree (MVPN profile 1). There are no P2MP mLDP trees in this example, although there is nothing precluding them from existing. CSR1 and CSR8 are both receivers for group 232.4.4.4 and signal their interest to the PEs using IGMPv3. The joins include the source 192.168.4.4, which is the only sender. The customer PEs will encapsulate this multicast traffic into GRE multicast using the MDT default group 232.0.0.255 (MVPN profile 0). We will check CSR10 as a quickly to verify its MDT status. CSR10 has VRF-aware PIM neighbors within the customer VPN.

```
CSR10#show ip pim mdt
```

```
* implies mdt is the default MDT, # is (*,*) Wildcard,
> is non-(*,*) Wildcard
```

MDT Group/Num	Interface	Source	VRF
* 232.0.0.255	Tunnel1	Loopback0	VPN

```
CSR10#show ip pim vrf VPN neighbor
```

```
PIM Neighbor Table
```

```
Mode: B - Bidir Capable, DR - Designated Router, N - Default DR Priority,
      P - Proxy Capable, S - State Refresh Capable, G - GenID Capable,
      L - DR Load-balancing Capable
```

Neighbor Address	Interface	Uptime/Expires	Ver	DR Prio/Mode
9.9.9.9	Tunnel1	01:51:51/00:01:35	v2	1 / S P G
6.6.6.6	Tunnel1	03:33:13/00:01:35	v2	1 / S P G

XRv11 receives a P(S,G) join from CSR7 for the default MDT. Customer AS 65000 is PIM-enabled for MVPN transport, as expected, so XRv11's only job is to continue building the P(S,G) tree towards the source, CSR10. XRv11's P(S,G) state shown below forwards traffic along the SPT towards the core carrier.

For brevity, we do not trace the entire P(S,G) join process; if XRv11 has the join, it is indicative of a successful configuration. Additional MVPN verifications are detailed in the corresponding chapter.

```
RP/0/0/CPU0:XRv11#show pim topology 232.0.0.255 10.10.10.10 | begin 232
(10.10.10.10,232.0.0.255)SPT SSM Up: 01:19:08
JP: Join(00:00:41) RPF: GigabitEthernet0/0/0/0.510,10.10.11.10 Flags:
GigabitEthernet0/0/0/0.571 01:19:08 fwd Join(00:03:14)
```

A quick check of CSR7's MDT status shows all neighbors are up. MDT 0 within the context of mLDP means the default MDT (MP2MP delivery tree). Even without verifying this, we could assume it was working based on the P(S,G) join above. If the core carrier's MDT is broken, the customer MDTs relying on it are, by extension, also broken.

```

```

When CSR4 starts sending traffic, CSR10 encapsulates it inside the default MDT and forwards it to XRv11. XRv11 forwards it to CSR7 so it enters the core carrier. These basic steps are not shown, and we skip to CSR7 for additional verification. Upon receipt, CSR7 encapsulates the traffic inside MPLS (LSM) with a single mLDP label allocated by CSR2. This is upstream towards the root, which is CSR3.

```

```

At this time, we will enable the capture inbound on CSR2 and use that to view the encapsulation as we did for unicast. We expect to see a single transport label (mLDP) after the layer 2 encapsulation with no customer carrier MPLS encapsulation, since that carrier is using MVPN profile 0 (no LSM). The output is described in detail next.

```
CSR4#ping 232.4.4.4 repeat 5 timeout 0
```

```

Jumping straight to the first set of MPLS labels, we see value 0x7DB (2011) used to send traffic towards the mLDP root (CSR3), using an upstream mLDP label allocated by CSR2 (yellow). This is the only label, and the assertion of the S-bit proves this. Immediately following this is a GRE/IP header with source 10.10.10.10 and destination 232.0.0.255, which represents the MDT source and default group, respectively (green). Following that is another IP packet, the customer ICMP ping, from 192.168.4.4 to 232.4.4.4 (cyan). There is significantly less MPLS interaction here since the core carrier uses a single label to transport the multicast between PEs (no PHP) but the customer carrier doesn't use LSM at all. The point of this demonstration was to show that the L3VPN encapsulation profile supports both unicast and multicast transport. Like any good CSC solution, the customer and core carrier forwarding mechanisms can be entirely different as well.

The final set of tests will quickly evaluate IPv6 unicast and multicast across the network. IPv6 SSM is used again in the customer network as transport and is encapsulated inside IPv4 GRE multicast at the customer PEs. Since the P(S,G) signaled is still IPv4-based, we don't need to retrace the signaling path for the IPv6 MVPN flow. We will perform a unicast capture first, and then validate the packet contents against the control-plane show commands. The IPv6 header is much larger to account for larger addresses, but decoding it is easier because the numbers are hexadecimal in the first place.

```

The core carrier label stack is {2008 5049} in yellow, the IP/GRE header is 10.10.10.10 -> 9.9.9.9 in cyan, the customer VPN label is 9009 in green, and the IPv6 header is FD00:192:168:4::4 -> FD00:192:168:8::8 in pink. We won't verify the ICMP ping because we initiated it and it's easily understood. We will verify it as quickly as possible using the most succinct show commands, for variation. The core carrier imposes two labels for traffic heading towards the remote PE, and this traffic was generated by the source PE sending traffic to the dynamic endpoints and imposing the VPN label for the customer route allocated by the remote PE (VPNv6). The colors in the EPC capture match the highlights below.

```

CSR7#show ip cef vrf CH 9.9.9.9

```

Unfortunately, IPv6 multicast does not appear to work. There is an RPF logic problem. When the last-hop router (egress customer PE) receives the MLDv2 SSM join from the customer, it thinks the RPF interface is the L3VPN encapsulation tunnel and not the MDT tunnel. The remote end (CSR10) never receives the PIMv6 (S,G) join since the egress PE isn't able to send it properly. Below, all RPF/C-MFIB related commands indicate that the L3VPNv6 tunnel is the RPF interface (Tunnel0) while the PIM neighbors form over the default MDT (Tunnel1).

```

```

Quickly checking IPv4, we see this is not a problem since the router knows that the RPF interface for multicast traffic within the VPN should be the MDT "emulated LAN". I believe the IPv6 support isn't fully implemented yet, because we clearly saw IPv4 multicast working earlier. Since there isn't an actual Tunnel0 or Tunnel1 interface, correcting this problem appears impossible at this time (no ability to enable PIM, adjust mroutes, etc).

36. Describe, implement, and troubleshoot IPv6 transition mechanisms

36.1 NAT44 and NAT444

NAT44 is synonymous with ordinary IPv4 NAT which has been around for many years. It is more accurately called NAT44 nowadays, implying an IPv4-to-IPv4 translation. With other mechanisms in existence, such as NAT64 (formerly NAT-PT) and NAT66 (also called Network Prefix Translation v6 or NPTv6), there needed to be a way to distinguish between them, preferably without inventing different names for each one. NAT444 just means doing NAT44 twice; this is common in carrier-grade NAT (CGN) or large scale NAT (LSN) architectures. LSN is the newer term which is more accurate, since CGN implies that NAT444 is only relevant in SP networks, which is false. This document uses both the CGN and LSN terms interchangeably. The lab is generally focused on NAT444 since NAT44 is a subcomponent of it, and having a separate NAT44 lab adds no value. In this setup, CSR1 through CSR7 serve as CPE routers for small businesses or homes. In common LSN architectures, these nodes will perform NAT44 from a private IP range on the inside (locally administered) to another private IP range on the outside (SP administered). The reason is that NAT overload gives us some ~65,000 connections per IP address using TCP/UDP port numbers as multiplexers, and assigning a real global address to a CPE router is viewed as wasteful. If each CPE received a public IPv4 address, their overload utilization would be much lower, which is highly inefficient compared to LSN. The LSN nodes, CSR8 through CSR10, each have real public addresses. They perform NAT44 again from the SP administered private addressing on the inside to public addressing on the outside. XRv1 and XRv2 are BGP routers that interact with the IPv4/v6 Internet simulator, XRv3. XRv4 has several VRFs to represent customer hosts, like residential laptops, and is used for testing only.

Several different NAT44 variations are tested here since we are performing NAT44 on ten different nodes. A summary of the variations is below. CSR8 provides a direct Ethernet service to its CPEs, while CSR9 and CSR10 provide PPPoE variations for broadband aggregation. The CPE inside addressing is in the 192.168.0.0/16 range, the SP-administered private addressing is in the 10.0.0.0/8 range, and the public addresses are in the 209.19.85.8/30 range.

1. CSR1: ACL with NAT pool, no overload
2. CSR2: Route-map with NAT pool, reversible
3. CSR3: HSRP (active) and NAT
4. CSR4: HSRP (standby) and NAT
5. CSR5: Route-map per interface with PBR input, overload
6. CSR6: Static NAT
7. CSR7: ACL with NAT overload, VRF-aware
8. CSR8: Route-map with NAT overload, CGN disabled
9. CSR9: Route-map per interface, overload, CGN enabled
10. CSR10: Route-map with NAT overload, CGN enabled, VRF-aware

The IS-IS and BGP configurations are not shown in this lab as they are very basic to enable reachability from the Internet to the public post-NAT444 IP addresses on the LSN nodes. IS-IS is used between the

LSN and Internet ASBRs to exchange LSN and Internet routes back and forth. CSR1's NAT configuration is very basic. NAT inside is enabled on the CPE LAN with NAT outside facing the SP. The NAT pool contains the outside addresses assigned by the SP. Assigning 100 addresses to a single CPE may seem wasteful, but since they are private addresses, it matters less.

```
! CSR1
interface GigabitEthernet2.514
 ip nat inside

interface GigabitEthernet2.518
 ip nat outside

ip nat pool NAT_POOL 10.1.8.100 10.1.8.199 prefix-length 24
ip nat inside source list ACL_NAT pool NAT_POOL
ip access-list standard ACL_NAT
 permit 192.168.1.0 0.0.0.255
```

We can verify the proper interface and pool configuration using the show commands below. We don't care about the statistical values just yet, but only that the names are correct.

```
R1#show ip nat pool name NAT_POOL
NAT Pool Statistics
Pool name NAT_POOL, id 1
```

	Assigned	Available
Addresses	1	99
UDP Low Ports	0	51200
TCP Low Ports	0	51200
UDP High Ports	0	6451100
TCP High Ports	0	6451100

(Low ports are less than 1024. High ports are greater than or equal to 1024.)

```
R1#show ip nat statistics | section interface
Outside interfaces:
 GigabitEthernet2.518
Inside interfaces:
 GigabitEthernet2.514
```

When using ACL-based NAT without overloading, non-extended NAT entries are automatically created. That is, when a host initiates a protocol-specific session to a remote destination (ping, telnet, etc), that entry is accounted for with a specific port/protocol mapping. However, the inside local to inside global mapping is also stored in the NAT table, which allows unsolicited inbound traffic from the outside. XRv4 sends some traffic to CSR8, the LSN node. CSR1 performs NAT44 to change XRv4's address to an available 10.1.8.0/24 address from the specified pool. Two entries are added to the table; one is fully extended (yellow), which contains the port/protocol information. The other is non-extended (green) which associates 10.1.8.100 with 192.168.1.14.

```
R1#show ip nat translations
```

Pro	Inside global	Inside local	Outside local	Outside global
---	10.1.8.100	192.168.1.14	---	---
icmp	10.1.8.100:37041	192.168.1.14:37041	10.1.8.8:37041	10.1.8.8:37041

Because of this non-extended (green) entry, CSR8 can reach into the CPE network and ping XRv4 using 10.1.8.100. The NAT order of operations states that packets arriving on an inside interface are subject to routing first, then NAT. Packets arriving on an outside interface are subject to NAT first, then routing. Therefore, packets sent to 10.1.8.100 are translated to destination 192.168.1.14 first, then routed, which means CSR1 is not replying to the pings (XRv4 is). We can prove this by performing an EPC capture on CSR1's inside LAN. We see five ICMP packets sourced from 10.1.8.8 destined for 192.168.1.14, and the five replies coming back. It is clear that CSR8 initiated this ping flow and that XRv4 responded, which shows the outside-to-inside reachability. This is often undesirable but is the default behavior of using a NAT ACL with a NAT pool without overloading enabled.

```
R8#ping 10.1.8.100
```

```
Type escape sequence to abort.
```

```
Sending 5, 100-byte ICMP Echos to 10.1.8.100, timeout is 2 seconds:
```

```
!!!!
```

```
Success rate is 100 percent (5/5), round-trip min/avg/max = 3/5/16 ms
```

```
R1#show monitor capture CAP buffer brief
```

#	size	timestamp	source	destination	protocol
0	118	0.000000	10.1.8.8	-> 192.168.1.14	ICMP
1	118	0.001007	192.168.1.14	-> 10.1.8.8	ICMP
2	118	0.001999	10.1.8.8	-> 192.168.1.14	ICMP
3	118	0.003006	192.168.1.14	-> 10.1.8.8	ICMP
4	118	0.003997	10.1.8.8	-> 192.168.1.14	ICMP
5	118	0.005004	192.168.1.14	-> 10.1.8.8	ICMP
6	118	0.005996	10.1.8.8	-> 192.168.1.14	ICMP
7	118	0.005996	192.168.1.14	-> 10.1.8.8	ICMP
8	118	0.007995	10.1.8.8	-> 192.168.1.14	ICMP
9	118	0.016997	192.168.1.14	-> 10.1.8.8	ICMP

When using a route-map with a NAT pool, this outside-to-inside reachability is disabled by default. We will demonstrate this on CSR2. The configuration is very similar, using a slightly different NAT pool to account for a separate Ethernet link from CSR8. The NAT ACL is wrapped in a route-map, which is normally used for multi-homing, but can also be used to hide this "outside-in" functionality.

```
! CSR2
```

```
interface GigabitEthernet2.524
 ip nat inside
```

```
interface GigabitEthernet2.528
```

```

ip nat outside

ip access-list standard ACL_NAT
 permit 192.168.2.0 0.0.0.255

route-map RM_NAT permit 10
 match ip address ACL_NAT

ip nat pool NAT_POOL 10.2.8.100 10.2.8.199 prefix-length 24
ip nat inside source route-map RM_NAT pool NAT_POOL

```

Sending traffic from XRv4 only generates a single fully-extended NAT translation entry, which prevents inside access from CSR8. However, CSR8 still gets ICMP echo-replies, but since outside-to-inside NAT did not occur (no matching entry), CSR2 locally responded to those pings.

```

R2#show ip nat translations
Pro  Inside global      Inside local      Outside local      Outside global
icmp 10.2.8.100:45233   192.168.2.14:45233 10.2.8.8:45233    10.2.8.8:45233
Total number of translations: 1

```

```

R8#ping 10.2.8.100
Type escape sequence to abort.
Sending 5, 100-byte ICMP Echos to 10.2.8.100, timeout is 2 seconds:
!!!!
Success rate is 100 percent (5/5), round-trip min/avg/max = 4/4/6 ms

```

This ping response on CSR2 is the result of the dynamic IP alias created for the inside global address. On static NAT mappings, we can disable it, but not on dynamic ones. Packets arrived on CSR2's outside interface and were subject to NAT before routing. There was no matching NAT entry for the unsolicited ICMP flow from CSR8, so CSR2 performs a routing lookup and sees the dynamic alias effectively as a connected route.

```

R2#show ip alias
Address Type      IP Address      Port
Interface         10.2.8.2
Dynamic           10.2.8.100
Interface         192.168.1.2
Interface         192.168.2.2

```

Using EPC, we can prove these pings are going to XRv4, and that CSR2 is responding. We see no packets sent to the inside LAN when CSR8 initiates the pings, which validates the statements above.

```

R2#show monitor capture CAP buffer brief
-----
#   size  timestamp      source      destination  protocol
-----
[no output]

```

For consistency with CSR1, we can explicitly enable outside-in connectivity when using route-maps using the “reversible” keyword. We enable this on CSR2 and retest. Now, XRv4’s flow has a second entry to account for the outside-originated traffic (the non extended one).

```
! CSR2
ip nat inside source route-map RM_NAT pool NAT_POOL reversible

R2#show ip nat translations
Pro  Inside global      Inside local      Outside local      Outside global
---  10.2.8.100          192.168.2.14      ---              ---
icmp 10.2.8.100:41137   192.168.2.14:41137 10.2.8.8:41137    10.2.8.8:41137
```

Pinging from CSR8 now shows up in CSR2’s capture after modifying the NAT configuration. Since there is a non-extended NAT entry, NAT sees a match, performs a translation, then routing occurs. This behavior is operationally identical to CSR1.

```
R8#ping 10.2.8.100
Type escape sequence to abort.
Sending 5, 100-byte ICMP Echos to 10.2.8.100, timeout is 2 seconds:
!!!!
Success rate is 100 percent (5/5), round-trip min/avg/max = 4/140/671 ms
```

```
R2#show monitor capture CAP buffer brief

```

Next, we will configure CGN on CSR8. There is a specific “CGN” mode of NAT which is discussed later, but the term is misleading because there is nothing “carrier-grade” about it. It just modifies the NAT process slightly; we will evaluate this on CSR9 and CSR10 later. CSR8, however, will just do NAT44 again with CSR1 and CSR2 10.1.8.0/24 and 10.2.8.0/24 subnets as inside addresses. These subnets were the outside NAT pools on the CPEs, but are viewed as inside addresses from the perspective of CSR8. The public address 209.19.85.8/32 is configured on a loopback so as not to waste public addressing on transit links with XRv2. CSR8 uses a route-map with overload, which means reversible NAT (outside-in) is not supported at all.

```

! CSR8
interface GigabitEthernet2.518
 ip nat inside

interface GigabitEthernet2.528
 ip nat inside

interface GigabitEthernet2.582
 ip nat outside

ip nat inside source route-map RM_NAT interface Loopback209 overload

ip access-list standard ACL_NAT
 permit 10.1.8.0 0.0.0.255
 permit 10.2.8.0 0.0.0.255

route-map RM_NAT permit 10
 match ip address ACL_NAT

```

We will perform a basic routing check on CSR8 to make sure it has Internet connectivity. The Internet consists of routes from AS 13 (13.0.0.0/8) while XRv1 and XRv2 summarize this into IS-IS from BGP. We confirm that CSR8 has the routing information and reachability via ping.

```

R8#show ip route 13.0.0.0 255.0.0.0
Routing entry for 13.0.0.0/8
  Known via "isis", distance 115, metric 30, type level-2

R8#ping 13.144.2.9 source loopback209
Type escape sequence to abort.
Sending 5, 100-byte ICMP Echos to 13.144.2.9, timeout is 2 seconds:
Packet sent with a source address of 209.19.85.8
!!!!
Success rate is 100 percent (5/5), round-trip min/avg/max = 2/147/724 ms

```

At this point, hosts behind CSR1 and CSR2 should have Internet reachability. Sending traffic from both LANs to the Internet, we check the NAT tables on CSR1, CSR2, and CSR8. Since CSR1 is using ACL-based NAT with pools, we see non-extended entries for outside-in traffic. Likewise on CSR2, using the route-map-based NAT pool technique with the “reversible” option, we see non-extended entries as well. CSR8 has two fully-extended entries that map the inside local addresses (inside global addresses from CSR1 and CSR2 perspectives) to the single public IP addressing using port overloading. Addresses are highlighted to show their position in the NAT tables. NAT444 derives its names from the original host being represented by three addresses, which implies NAT44 performed twice. In this case, 192.168.1.14

is also seen as 10.1.8.100 and 209.19.85.8. 192.168.2.14 is also seen as 10.2.8.100 and 209.19.85.8; the hierarchy of LSN allows better IPv4 address conservation.

```
R1#show ip nat translations

```

Next, we will configure CSR3 and CSR4 concurrently. Stateful NAT (SNAT) does not appear to be supported on the CSR1000v, which was the intent of this setup. We can configure a SNAT-like setup anyway. The XRv4 VRF host is on a shared LAN with both routers; CSR3 and CSR4 run HSRPv2 to determine default gateway status for XRv4. Each one tracks the presence of the default route, which is negotiated with IPCP (via PPPoE). CSR3 is active while CSR4 is standby based on priorities. The configuration is identical on CSR3 and CSR4 with the exception of the HSRP priority and interface enumerations, so only CSR3 is shown. Only pertinent configurations are shown; both routers use basic ACL NAT with overload, which means outside-in traffic is not permitted. For PPPoE technical details, review the specific chapter on this topic.

```
! CSR3
interface GigabitEthernet2.534
 ip nat inside
 standby version 2
 standby 344 ip 192.168.34.254
 standby 344 priority 105
 standby 344 preempt
 standby 344 name SITE34
 standby 344 track 9 decrement 10

interface Dialer3
 ip address negotiated
 ip nat outside
 ppp ipcp route default

interface GigabitEthernet2.539
 pppoe-client dial-pool-number 3

track 9 ip route 0.0.0.0 0.0.0.0 reachability
```

```
ip nat inside source list ACL_NAT interface Dialer3 overload
ip access-list standard ACL_NAT
 permit 192.168.34.0 0.0.0.255
```

In order for basic reachability to exist with the LSN node, we have to configure CSR9 also. CSR9 hands out IP addresses via IPCP using a local address pool. This keeps all of the PPPoE clients in the same “subnet”, but they cannot reach each other since PPP only installs host routes between connected endpoints. All of CSR9’s PPPoE clients are in different VLANs, so we can set very strict session limits for broadband aggregation. For now, we will not configure any NAT on CSR9 so that we can verify CSR3 and CSR4 in isolation.

```
! CSR9
bba-group pppoe PPPOE_LSN
 virtual-template 345
 sessions per-mac limit 1
 sessions per-vlan limit 1

interface Virtual-Template345
 peer default ip address pool PPPOE_POOL

interface GigabitEthernet2.539
 pppoe enable group PPPOE_LSN

interface GigabitEthernet2.549
 pppoe enable group PPPOE_LSN
```

After configuring this, CSR3 and CSR4 should establish PPPoE sessions with CSR9. They both install static default routes as supplied by IPCP, using the PPPoE server as a next-hop. For brevity, we will verify the client details on CSR3 only. Recursive routing lookups show that the PPPoE server IP address is known via a host route, also installed by PPP.

```
R3#show pppoe session
 1 client session
```

Uniq ID	PPPoE SID	RemMAC LocMAC	Port	VT	VA VA-st	State Type
N/A	26	0050.56a9.d672 0050.56a9.8ccf	Gi2.539	Di3	Vi1	UP

```

Now, we will send traffic from XRv4 to CSR9's PPPoE server address. We expect to see NAT entries on CSR3 only (no SNAT supported) since it is the active HSRP gateway. Notice that there is only one fully-extended entry; whether using an ACL or route-map, outside-in traffic is non-reversible when overloading is enabled. Non-extended entries don't exist since the NAT mappings happen at layer 4, not layer 3.

```
R3#show ip nat translations
Pro  Inside global      Inside local          Outside local          Outside global
icmp 10.34.59.101:1       192.168.34.14:24753  10.34.59.9:24753      10.34.59.9:1
Total number of translations: 1
```

```
R4#show ip nat translations
```

```
Total number of translations: 0
```

As a quick test of HSRP, we will break CSR3's PPPoE connection by shutting down its dialer interface. CSR4 becomes the active HSRP gateway since CSR3 loses its default route and decrements its HSRP priority to less than CSR4's value. We confirm this on CSR3 and CSR4. This proves that the default-route tracker works properly.

```
R3#show standby brief
```

```
                P indicates configured to preempt.
                |

```
Total number of translations: 1
```

Before continuing, we bring CSR3 back into the PPPoE network. CSR9 now allocates a new address of 10.34.59.103, which is relevant for NAT44 discussed next.

```
R3#show ip interface brief dialer 3
```

Interface	IP-Address	OK?	Method	Status
Protocol				
Dialer3	10.34.59.103	YES	IPCP	up

Next, we can configure NAT on CSR9. We will introduce a new feature; route-map multi-homing. Since CSR9 is connected to multiple BGP gateway routers, CEF will split traffic between the two assuming ECMP is in play. Using route-maps, we can reference the same inner ACL to match the inside local addresses (from the PPPoE local pool). CSR9 has two public IP addresses available: 209.19.85.9 and 209.19.85.11. Traffic routed to XRv1 (east) will use .9, while traffic routed to XRv2 (west) will use .11. CSR9 is not using policy-routing to force traffic in a given direction; this just specifies the post-NAT address, or packet source, based on the CEF load-sharing decision process. Since inside NAT happens before routing, the outgoing interface has already been identified, implying that the NAT process can use this as match criteria in the route-map.

```
! CSR9
```

```
interface Virtual-Template345
 ip nat inside
```

```
interface GigabitEthernet2.591
 ip nat outside
```

```
interface GigabitEthernet2.592
 ip nat outside
```

```
ip access-list standard ACL_NAT
 permit 10.34.59.0 0.0.0.255
```

```

route-map RM_NAT_EAST permit 10
  match ip address ACL_NAT
  match interface GigabitEthernet2.591

route-map RM_NAT_WEST permit 10
  match ip address ACL_NAT
  match interface GigabitEthernet2.592

ip nat inside source route-map RM_NAT_EAST interface Loopback209 overload
ip nat inside source route-map RM_NAT_WEST interface Loopback211 overload

```

We will also introduce the concept of CGN. There are two modes of NAT supported on the CSR1000v: traditional and CGN. Traditional NAT stores the outside local/global address per flow which determine the final destination an inside host is trying to reach. Conversely, it shows the source address of returning packets. CGN does not track this at all; this conserves memory, which allows NAT to scale better. The outside local/global address are irrelevant since a CGN device can look at the destination address/port of a returning packet and map it to an existing NAT entry. Enabling CGN automatically removes support for NAT outside mappings, so only the first command is required. The biggest downside of CGN in an enterprise environment is that the entire “ip nat outside” syntax tree disappears. Because there are no outside mappings, this feature is unsupported. Outside mappings are not commonly used anyway, and certainly not needed for LSN.

```

! CSR9
ip nat settings mode cgn
no ip nat settings support mapping outside

```

We expect traffic to be translated from 10.34.59.103 (CSR3’s PPPoE client address) to either 205.19.85.9 or .11 depending on the CEF decision. To demonstrate both NAT policies, we will destine traffic to two different Internet destinations from the same source. CSR9’s FIB says that traffic to 13.144.2.1 will be routed east to XRv1, while .9 will be routed west to XRv2. Yellow (east) and green (west) are used throughout this test to differentiate flows.

```

R9#show ip cef exact-route 10.34.59.103 13.144.2.1
10.34.59.103 -> 13.144.2.1 =>IP adj out of GigabitEthernet2.591, addr
10.9.11.11

```

```

R9#show ip cef exact-route 10.34.59.103 13.144.2.9
10.34.59.103 -> 13.144.2.9 =>IP adj out of GigabitEthernet2.592, addr
10.9.12.12

```

XRv4 will send pings to both destinations at the same time. We already know that CSR3 is going to translate both flows to an outside address of 10.34.59.103 based on its IPCP address; we do not verify this again. On CSR9, we see two separate NAT entries with those final Internet destinations (outside global) not tracked at all. CGN simply does not care about those Internet destinations. The traffic to 13.144.2.1 is source-translated to 209.19.85.9, while traffic to 13.144.2.9 is source-translated to

209.19.85.11. This is expected per the NAT policies; since the route-maps used interfaces as match criteria, different post-NAT addresses were used based on the routing decisions. The NAT statistical refcounts show that there is one translation entry per rule. This is a quick way to verify there is some kind of load sharing happening.

```
R9#show ip nat translations
Pro  Inside global      Inside local          Outside local          Outside global
icmp 209.19.85.11:1    10.34.59.103:4       ---                    ---
icmp 209.19.85.9:1    10.34.59.103:3       ---                    ---
Total number of translations: 2
```

```
R9#show ip nat statistics | include ref
[Id: 3] route-map RM_NAT_EAST interface Loopback209 refcount 1
[Id: 4] route-map RM_NAT_WEST interface Loopback211 refcount 1
```

We will use EPC to verify this by capturing outbound on CSR9 using both upstream interfaces. We look at the destination MAC address to verify the directionality from CSR9's perspective. The buffer brief shows the same information as the NAT table, where packets from different post-NAT addresses are used when traffic is destined differently. EPC happens after routing and NAT, which is why we see post-NAT sources.

```
R9#show monitor capture CAP buffer brief
```

#	size	timestamp	source	destination	protocol
2	118	2.249987	209.19.85.9	-> 13.144.2.1	ICMP
3	118	2.252977	209.19.85.9	-> 13.144.2.1	ICMP

10	118	5.988999	209.19.85.11	-> 13.144.2.9	ICMP
11	118	5.998001	209.19.85.11	-> 13.144.2.9	ICMP

The ARP entries are shown below for verifying the destination MAC addresses of XRv1 and XRv2 in the packet captures. We can confirm the statements above by verifying the MAC addresses in addition to the IP addresses. This is just to confirm that the packets are being sent out of the proper interfaces; only one of each packet is shown. The same two packets (#6 and #7) are highlighted again below.

```

```

Next, we will configure CSR6 and CSR7 for NAT44 operations. They will be connecting to CSR10 via PPPoE as well, but will use static addressing along with default static routes in lieu of IPCP. All of the PPPoE clients will share a VLAN as well. CSR6 will use static one-to-one NAT for its single LAN client; notice that it is using a new inside global address of 10.6.10.14. This address doesn't fit nicely into any subnet anywhere, and it doesn't have to. CSR7 will use the ACL NAT with overload, much like CSR3 and CSR4. The difference is that CSR7 will do this inside of a VRF just for variety, but the configuration is very similar.

```
! CSR6
interface GigabitEthernet2.564
 ip nat inside

interface Dialer6
 ip nat outside

ip nat inside source static 192.168.6.14 10.6.10.14
ip route 0.0.0.0 0.0.0.0 10.56.70.10 10

! CSR7
interface GigabitEthernet2.574
 vrf forwarding CPE
 ip nat inside

interface Dialer7
 vrf forwarding CPE
 ip nat outside

ip nat inside source list ACL_NAT interface Dialer7 vrf CPE overload
ip access-list standard ACL_NAT
 permit 192.168.7.0 0.0.0.255
```

```
ip route vrf CPE 0.0.0.0 0.0.0.0 10.56.70.10 10
```

In order for the PPPoE sessions to come up, we have to configure CSR10. Like CSR9, we will ignore the CGN configuration on CSR10 for now. CSR10 will also be performing VRF operations so we will configure that now as well. Notice that the per-VLAN PPPoE session limit is 3 because all three clients share a LAN, but the per-MAC limit is still 1. One key point is that CSR10 needs a route back to CSR6's inside global address representing XRv4, since it was a made-up address.

```
! CSR10
interface Virtual-Template567
  vrf forwarding LSN

bba-group pppoe PPPOE_LSN
  virtual-template 567
  sessions per-mac limit 1
  sessions per-vlan limit 3

interface GigabitEthernet2.556
  pppoe enable group PPPOE_LSN

ip route vrf LSN 10.6.10.0 255.255.255.0 10.56.70.6
```

We quickly verify the PPPoE sessions are up on CSR10, then perform a quick NAT test from XRv4 to the PPPoE server address via CSR6 and CSR7. Notice that both PPPoE clients are in the same VLAN as expected. CSR10 is not performing NAT currently as we are verifying CSR6 and CSR7 first. Because CSR6 is using static NAT with a non-extended entry, traffic would be allowed in from CSR10. We won't test this again since we tested it with CSR1 and CSR2 earlier, but the NAT table clearly shows the non-extended (permanent) entry. Both CSR6 and CSR7 show the same outside global address of CSR10's PPPoE server address. The inside local from each represents the XRv4 VRF that is used for testing, and the inside global is the post-NAT address.

```
R10#show pppoe session
  2 sessions in LOCALLY_TERMINATED (PTA) State
  2 sessions total
```

Uniq ID	PPPoE SID	RemMAC LocMAC	Port	VT	VA VA-st	State Type

```

Next, we will configure CGN on CSR10. Using CGN mode, we disable all outside local/global address tracking. We will use an overloaded route-map VRF-aware configuration on CSR10 for variety. The behavior is operationally equivalent to ACL-based overload. The NAT ACL must account for the bogus inside global addresses offered by CSR6 as well as the general PPPoE client subnet used by CSR7.

```
! CSR10
interface GigabitEthernet2.501
 vrf forwarding LSN
 ip nat outside

interface Virtual-Template567
 ip nat inside

ip access-list standard ACL_NAT
 permit 10.56.70.0 0.0.0.255
 permit 10.6.10.0 0.0.0.255

route-map RM_NAT permit 10
 match ip address ACL_NAT

ip nat settings mode cgn
no ip nat settings support mapping outside
ip nat inside source route-map RM_NAT interface Loopback209 vrf LSN overload
```

Testing connectivity from the XRv4 clients all the way to the Internet, we can see two NAT entries on CSR10. Since CSR10 is single-homed to XRv1, there is no need for interface matching in the route-map as demonstrated on CSR9. All post-NAT addresses (inside global) use 209.19.85.10, regardless of inside local or FIB decision.

```
R10#show ip nat translations
Pro  Inside global      Inside local      Outside local      Outside global

Total number of translations: 2
```

Last, we will configure CSR5. It is multi-homed with two PPPoE connections, one to CSR9 and one to CSR10. It conforms to the address policies of each; that is, it receives an IPCP address from CSR9, while using static addressing towards CSR10. No default routes exist on CSR5 since we will use PBR in conjunction with NAT to influence traffic patterns on a per-source basis. This cannot be achieved without PBR since we are trying to achieve sourced-based routing. Specifically, because inside NAT happens before routing, the NAT process relies on the RIB process to tell it the outgoing interface. Using PBR, we can set this outgoing interface or next-hop, then match it in a NAT route-map to select the

inside global address. In this case, sources in 192.168.5.0/25 (bottom half) will use Dialer59's dynamic PPPoE pool address and be sent to CSR9. The addresses within 192.168.5.128/25 (top half) will use Dialer50's static address and be sent to CSR10. The NAT route-maps don't need to match source addresses because in this case, we know CSR5 has no routes, and can only route via PBR. Since PBR is only matching the sources we care about, we can omit an ACL with our NAT route-maps, despite it being a dangerous practice.

```
! CSR5
interface Dialer50
 ip nat outside

interface Dialer59
 ip nat outside

ip access-list standard ACL_EAST_TOP
 permit 192.168.5.128 0.0.0.127
ip access-list standard ACL_WEST_BOTTOM
 permit 192.168.5.0 0.0.0.127

route-map RM_PBR permit 10
 match ip address ACL_WEST_BOTTOM
 set interface Dialer59
route-map RM_PBR permit 20
 match ip address ACL_EAST_TOP
 set interface Dialer50

route-map RM_EAST permit 10
 match interface Dialer50
route-map RM_WEST permit 10
 match interface Dialer59

interface GigabitEthernet2.554
 ip nat inside
 ip policy route-map RM_PBR

ip nat inside source route-map RM_EAST interface Dialer50 overload
ip nat inside source route-map RM_WEST interface Dialer59 overload
```

When XRv4 sends traffic from 192.168.5.14 and 192.168.5.214, we see two separate inside global addresses for each. The east entry is shown in yellow and the west entry in green. PBR directed traffic from .14 to use CSR9 as the next-hop and .214 to use CSR10 as the next-hop. NAT honored those routing decisions by selecting the proper inside global (post-NAT) address. The PBR packet counters are useful to ensure the policies are configured properly.

```
R5#show ip nat translations
Pro  Inside global      Inside local      Outside local      Outside global
icmp 10.34.59.105:1     192.168.5.14:53425 13.144.2.1:53425 13.144.2.1:1
icmp 10.56.70.5:1     192.168.5.214:49329 13.144.2.1:49329 13.144.2.1:1
```

Total number of translations: 2

```
R5#show route-map RM_PBR
route-map RM_PBR, permit, sequence 10
  Match clauses:

route-map RM_PBR, permit, sequence 20
  Match clauses:
    ip address (access-lists): ACL_EAST_TOP
  Set clauses:
    interface Dialer50
  Policy routing matches: 5 packets, 590 bytes
```

We can confirm that the packets were routed of the proper interfaces by checking CSR9 and CSR10. Each one should only have one NAT entry; CSR10 has the east entry and CSR9 has the west entry. Notice that the inside local on the CGN router is the same as the inside global on the CPE router. As expected, CSR9 selects one of its global addresses based on its ECMP scheme, while CSR10 uses its only global address. Again, neither CGN router stores outside local/global address information.

```
R9#show ip nat translations
Pro  Inside global      Inside local      Outside local      Outside global

Total number of translations: 1
```

NAT also supports port forwarding for specific outside to inside communications. This might be valuable for VPN/remote access from the outside. Although unrelated to CGN/LSN, it is a common NAT technique in general. We will quickly demonstrate this on CSR1. This will allow outside hosts, such as CSR8, to access internal resources on specific TCP/UDP ports. We can specify the outside interface or an IP address. If the inside global address is not already present on the router (such as 10.1.8.22), the router automatically creates a dynamic alias for it. In this example, we allow outside routers to access XRv4 via telnet on port 2300 when using CSR1's outside address. Alternatively, they can use SSH on port 2200 using a new address 10.1.8.22.

```
! CSR1
ip nat inside source static tcp 192.168.1.14 23 interface Gig2.518 2300
ip nat inside source static tcp 192.168.1.14 22 10.1.8.22 2200 extendable
```

```
R1#show ip alias
Address Type      IP Address      Port
Interface         10.1.8.1
```

```
Dynamic          10.1.8.22
Interface        192.168.1.1
Interface        192.168.1.2
```

Testing this from CSR8, it can access XRv4 via telnet and SSH. This requires that XRv4 be configured as a telnet and SSH server (not shown).

```
R8#telnet 10.1.8.1 2300
Trying 10.1.8.1, 2300 ... Open

R8#ssh -l cisco -p 2200 10.1.8.22
IMPORTANT: READ CAREFULLY
[snip]
```

CSR1 shows the non-extended entries, which we must have to allow the outside unsolicited traffic. The fully extended entries represents actual NAT sessions currently in place: telnet is highlighted green and SSH is highlighted yellow. Specific sessions spawn these fully-extended entries on a per-session basis. The outside local/global address will always be the initiator of the port-forwarded session, which is CSR8 in this case.

```
R1#show ip nat translations tcp
Pro  Inside global      Inside local      Outside local      Outside global
tcp  10.1.8.1:2300       192.168.1.14:23   ---               ---

tcp  10.1.8.1:2300      192.168.1.14:23   10.1.8.8:33914    10.1.8.8:33914
```

Although not significant to NAT44, IPv6 can run alongside this architecture assuming all devices are dual-stack. Only IPv4 is subject to NAT44, so IPv6 reachability from XRv4's VRFs to the Internet is not impacted. All transports, such as Ethernet, PPPoE, etc can carry IPv6 and NAT44 will simply ignore it. The IPv6 routing in this design is very sloppy to create additional complexity (more elegant ways exist to issue IPv6 prefixes over PPPoE and are shown in the PPPoE section). The routing between CSR8 and its CPEs (CSR1 and CSR2) is static, which is redistributed into IS-IS and later BGP. CSR9 uses OSPFv3 to learn the downstream IPv6 prefixes from CPE devices. PPPoE IPv6 client does not appear to work at all inside a VRF, so CSR7 has no IPv6 connectivity. The NAT64 section details the translation mechanisms for interworking between IPv4 and IPv6 to support LSN architectures. The point is that NAT44 is not in play when native IPv6 hosts are trying to reach the IPv6 Internet.

Additional Reading – Reference configurations "Isn-444"

36.2 NAT64 and NAT464

This test continues from the previous topology with some modifications. From an LSN perspective, a common use case of NAT64 is to deploy a NAT464 architecture. Like NAT444, NAT still occurs twice, but NAT464 introduces NAT64 at the CPE and the LSN. The original IPv4 packet is translated to IPv6 by the CPE, transiting the PE-CE link as IPv6. This can help bypass any firewall rules for east-west traffic that might be filtered by private IPv4 addressing. In the examples seen in this lab, notice that IPv4 has been

completed removed between the CPE and LSN nodes as it is no longer needed. The LSN translates the IPv6 traffic from the CPE back to IPv4 so it can be routed to the IPv4 Internet. Native IPv6 traffic, like before, it not subject to NAT64 and would be routed normally to the IPv6 Internet. The network diagram is below; the same architecture is used for NAT464 as was used for NAT444.

NAT64 comes in two variants: stateful and stateless. These are quickly described below and are demonstrated in great detail later.

1. **Stateful:** Like traditional NAT, this feature maintains a state table of all translations. This includes original and translated IPv4 and IPv6 addresses. Classic NAT features such as port-overloading, ACL-based matching, and static NAT are supported. Because overload is supported, address conservation is good use-case.
2. **Stateless:** This feature maps IPv4 addresses directly into IPv6 addresses and does so without maintaining any state in the router. IPv4 sources and destinations can be configured to share a common prefix or use different ones. This is much less computationally expensive than stateful NAT. There is no conversation of addressing since there is no concept of “overloading”.

On CSR1, where NAT64 will transform IPv4 into IPv6 for traffic heading towards the IPv4 Internet, we will configure stateless NAT64. This is a good option for CPE routers as it is less computationally expensive and less memory hungry. Aside from enabling NAT64 on the interfaces (IPv6 must be enabled

on both the v4 and v6 facing links), there are three key commands. First, we must define a NAT64 prefix. Both the IPv4 source and destination will be mapped to this prefix, and the prefix can vary in length. I find it most straightforward to use a /96 as the IPv4 address will always be encoded into the lowest-order 32 bits. The NAT64 “route” command adds a static route to the IPv4 RIB that directs traffic towards the NAT virtual interface (NVI). This forces traffic towards 13.0.0.0/8 to be NAT64’ed rather than routed normally, which is the same thing that happens for 3001::/96 when the NAT64 prefix is defined. A default route cannot be used for the NAT64 IPv4 route, so we must be selective; this is not totally realistic as the CPE should have a default route to cover all IPv4 prefixes on the Internet. The final IPv6 route is critical from a routing perspective. Since the destination and source both fit into 3001::/96, the router needs to have a more specific route to the destination prefixes. There is a 3001::/96 in the IPv6 RIB directing IPv6 traffic to the NVI, so the router needs a longer match to direct traffic to CSR8. Since the IPv4 destination always begins with 13, I create a route that matches this first octet, and is therefore 8 bits longer than the existing /96.

```
! CSR1
interface GigabitEthernet2.514
  nat64 enable
  ipv6 address FE80::1 link-local
  ipv6 nd ra suppress all

interface GigabitEthernet2.518
  nat64 enable
  ipv6 address FE80::1 link-local
  ipv6 nd ra suppress all

nat64 prefix stateless 3001::/96
nat64 route 13.0.0.0/8 GigabitEthernet2.518
ipv6 route 3001::D00:0/104 GigabitEthernet2.518 FE80::8
```

First, we will verify the NAT64 stateless prefix. If the prefix was invalid or undefined, this output would reveal that issue. Both the v4 and v6 interfaces are using this prefix since we did not define interface-specific prefixes for this test.

```
R1#show nat64 prefix stateless global
Global Stateless Prefix: is valid, 3001::/96
IFs Using Global Prefix
  Gi2.514
  Gi2.518
```

Next, we verify that the NAT64 route is correct. It is mapped to the global prefix, which means traffic towards 13.0.0.0/8 will have its IPv4 source/destination encoded into 3001::/96 when it is sent into the IPv6 network.

```
R1#show nat64 routes prefix 13.0.0.0/8
IPv4 Prefix      Adj. Address      Enabled Output IF
```

```

Global IPv6 Prefix
13.0.0.0/8      0.0.0.5      TRUE      Gi2.518
TRUE      3001::/96

```

```

R1#show ip route 13.0.0.0 255.0.0.0
Routing entry for 13.0.0.0/8
  Known via "static", distance 1, metric 0
  Routing Descriptor Blocks:
    * 0.0.0.5, via NVI0
      Route metric is 0, traffic share count is 1

```

Last, we verify the IPv6 route. Because all post-NAT64 traffic will have an IPv6 destination beginning with 3001::/96, followed by 8-bits representing the first IPv4 octet, we crafted a longer-match /104 route. When the router tries to send traffic towards this final destination, it sends it to CSR8's LL address. Without this manual route, traffic would loop (in software) back into the NVI by following the /96 and be dropped.

```

R1#show ipv6 route 3001::/96 longer-prefixes | begin Appl
a - Application
S   3001::/96 [1/0]
    via ::42, NVI0
S   3001::D00:0/104 [1/0]
    via FE80::8, GigabitEthernet2.518

```

From XRv4, I will send some large ping packets so they are easy to see. Using EPC on CSR1, we can confirm that NAT64 is working correctly. Since this is a stateless translation, there is no translation table associated, so real-time verification is preferred. CSR8 has not been configured for NAT64 yet, so we do not expect the ping to succeed, but we can verify that CSR1 is translating the packets properly. Capturing inbound IPv4 and outbound IPv6 on CSR1, we see the same packet twice. First, we see the original IPv4 source/destination as originated by XRv4. After NAT64 occurs, those same 32-bit addresses are encoded inside the IPv6 prefix 3001::/96 as shown in the outgoing IPv6 packet. Sources are in yellow and destinations are in green. Notice that, since a single global prefix was defined, both the source and destination addresses are contained within the same prefix. This can complicate routing significantly in large networks by making aggregation difficult.

```

```

NAT64 keeps track of packet counters as well, which is a quick way to verify NAT64 operation without EPC. The number says 13 only because I sent several other pings while testing. This output indicates a problem because packets are being translated v4 to v6, but not vice versa, which indicates a lack of bidirectional reachability. This is expected since the rest of the network has not been configured.

```
R1#show nat64 statistics prefix stateless 3001::/96

  Packets dropped: 0
```

Before configuring CSR8, we will configure CSR2 with stateless NAT64 using a variation of the method above. The interfaces are almost identical except CSR2 uses an interface-level prefix of length /32. This would allow a multi-homed CPE (like CSR5) to use different NAT64 prefixes for different ISPs if necessary. When a NAT64 prefix length other than /96 is used, two things change. First, bits 64 to 71, inclusive (8 bits), are fixed to 0, which are called universal-bits (u-bits); these are not well documented and are likely reserved for future use. The IPv4 addresses are encoded immediately following the prefix, putting it at bits 32 to 63, inclusive. Unlike the /96, the IPv4 address is in the middle of the IPv6 address, but still technically following the network prefix as it did for the /96. These fields are discussed more when the packet capture is examined, but the immediate relevance is building the IPv6 static route correctly. Without it, NAT64 cannot route traffic upstream. By specifying a v6v4 prefix at the link level and a v4v6 prefix globally, we can effectively use different IPv6 source/destination addresses for my post-NAT traffic. This resolves the network scalability issues related to aggregation we observed on CSR1.

```
! CSR2
interface GigabitEthernet2.524
  nat64 enable
  ipv6 address FE80::2 link-local
  ipv6 nd ra suppress all

interface GigabitEthernet2.528
  nat64 enable
  nat64 prefix stateless v6v4 3002::/32
  ipv6 address FE80::2 link-local
  ipv6 nd ra suppress all
```

```

nat64 prefix stateless v4v6 2222::/32
nat64 route 13.0.0.0/8 GigabitEthernet2.528
ipv6 route 3002:0:D00::/40 GigabitEthernet2.528 FE80::8

```

We will quickly verify the configuration as we did for CSR1. First, we verify that the interface-level prefix is enabled and valid. This v6v4 prefix will determine the post-NAT64 IPv6 destination addresses. The v4v6 global prefix will determine the post-NAT64 IPv6 source addresses.

```

R2#show nat64 prefix stateless v6v4 interfaces
v6v4 Stateless Prefixes
Interface
  NAT64 Enabled Global Prefix
GigabitEthernet2.528
  TRUE FALSE 3002::/32

```

```

R2#show nat64 prefix stateless v4v6 global
Global v4v6 Stateless Prefix: is valid, 2222::/32
IFs Using Global Prefix
  Gi2.524
  Gi2.528

```

Next, we confirm that the NAT64 IPv4 route is directing traffic for 13.0.0.0/8 to the NVI. This is identical to CSR1 and required to direct incoming IPv4 traffic to the NAT64 process.

```

R2#show ip route 13.0.0.0 255.0.0.0
Routing entry for 13.0.0.0/8
  Known via "static", distance 1, metric 0
  Routing Descriptor Blocks:
    * 0.0.0.1, via NVI0
      Route metric is 0, traffic share count is 1

```

Last, we confirm that the IPv6 static route is directing traffic for post-NAT IPv6 flows towards CSR8, rather than looping it back into the NVI. This is the same type of configuration required on CSR1.

```

R2#show ipv6 route 3002::/32 longer-prefixes | begin Appl
  a - Application
S   3002::/32 [1/0]
    via ::44, NVI0
S   3002:0:D00::/40 [1/0]
    via FE80::8, GigabitEthernet2.528

```

I begin sending large pings from XRv4 through CSR2. The NAT64 statistics are increasing, which suggests that it is working. Again, packets are being translated v4 to v6, but not vice versa, which implies a unidirectional forwarding path. Notice that we specifically check the v4v6 prefix of 2222::/32 since the only functional NAT64 direction is v4 to v6 at this point.

```

R2#show nat64 statistics prefix stateless v4v6 2222::/32
NAT64 Statistics
2222::/32:
  Packets translated (IPv4 -> IPv6)
    Stateless: 5
    Stateful: 0
    MAP-T: 0
  Packets translated (IPv6 -> IPv4)
    Stateless: 0
    Stateful: 0
    MAP-T: 0
  Packets dropped: 0

```

Using EPC in the same manner as on CSR1, we can see the IPv4 to IPv6 translation. Source addresses are yellow and destination addresses are green. The IPv4 address is embedded in a different spot as a result of the NAT64 prefix length. The u-bits and suffix are all zeroes as well, but of greater significance, stateless NAT64 is working. The most significant piece of this output is the difference between the IPv6 source and destination prefixes.

```

R2#show monitor capture CAP buffer detailed

```

Next, we will configure NAT64 on CSR8, which is an LSN node. This will translate IPv6 traffic from the customers CSR1 and CSR2 into public IPv4 traffic that can be used on the IPv4 Internet. As an LSN, CSR8 should be conservative with IPv4 addressing, so it will use stateful NAT64 to overload a small set of public IPv4 addresses using port numbers as differentiators. Defining an IPv4 pool is similar to regular NAT44, and the pool size is limited to a single IPv4 address. The IPv6 ACL matches the traffic candidate for NAT64, and because the CPEs are performing stateless NAT64, we can create very generic rules. The source/destination of the IPv6 packets from CSR1 and CSR2 are highly deterministic since we know the NAT64 stateless prefixes in use by CSR1 and CSR2. Last, we must define a NAT64 stateful prefix on CSR8. Like the stateless prefix, this creates a static route to the NVI so IPv6 traffic for these destinations can be NAT64'ed. I use per-interface prefixes since the CPEs are using different NAT64 prefixes; the formats should match so addressing can be derived properly. CSR8 needs to know where the IPv4 address is encoded within the IPv6 address to decode it properly, so a generic prefix only works when all CPEs are using the same prefix length. The two IPv6 static routes are used to direct traffic back to the CPEs.

Notice that CSR1's route is somewhat complex since it encompasses the entire NAT64 prefix, then uses a more specific match to keep traffic from looping into the NVI. CSR2 uses an entirely different source IPv6 range, which is cleaner from a routing perspective.

```
! CSR8
interface GigabitEthernet2.518
  nat64 enable
  nat64 prefix stateful 3001::/96
  ipv6 address FE80::8 link-local

interface GigabitEthernet2.528
  nat64 enable
  nat64 prefix stateful 3002::/32
  ipv6 address FE80::8 link-local

interface GigabitEthernet2.582
  nat64 enable
  ipv6 address FE80::8 link-local

ipv6 access-list ACL_LSN_64
  permit ipv6 3001::/96 3001::/96
  permit ipv6 2222::/32 3002::/32

nat64 v4 pool NAT64_POOL 209.19.85.8 209.19.85.8
nat64 v6v4 list ACL_LSN_64 pool NAT64_POOL overload

ipv6 route 2222::/16 GigabitEthernet2.528 FE80::2
ipv6 route 3001::C0A8:100/120 GigabitEthernet2.518 FE80::1
```

One interesting behavior of stateful NAT64 is that the addresses contained within the IPv4 pool cannot exist on any interfaces, even shutdown ones. This is because NAT64 installs an NVI route to the pool addresses which forces them into the NAT process; having a connected route already in the routing table would break this logic. I completely remove Loopback209 (not shown) so that the command below is accepted.

```
R8(config)#nat64 v4 pool NAT64_POOL 209.19.85.8 209.19.85.8
%NAT64: The range 209.19.85.8-209.19.85.8 cannot contain an interface address
(found overlap with address on interface Loopback209)
```

Unlike stateless NAT64, we did not need to add a static route to forward traffic further upstream. CSR8 learns an IS-IS summary route for 13.0.0.0/8 from XRv2, which is sufficient for traffic towards the Internet from the LSN.

```
R8#show ip route 13.0.0.0 255.0.0.0
Routing entry for 13.0.0.0/8
  Known via "isis", distance 115, metric 20, type level-2
```

```
Redistributing via isis 1112
Last update from 10.8.12.12 on GigabitEthernet2.582, 01:56:07 ago
Routing Descriptor Blocks:
* 10.8.12.12, from 0.0.0.0, 01:56:07 ago, via GigabitEthernet2.582
  Route metric is 20, traffic share count is 1
```

Return traffic is broken as a result of removing Loopback209. This was advertised into IS-IS earlier which ultimately allowed the Internet to know about it. Although summarization was used in previous labs to influence routing decisions, I am illustrating a situation where such alternate paths would not exist. There is technically a /30 covering this prefix, known to XRv3, but that is beyond the scope of the current problem.

```
RP/0/0/CPU0:XRv3#show cef 209.19.85.8/32
%Prefix not found or IP is not running. VRF default.
```

```
RP/0/0/CPU0:XRv3#show cef 209.19.85.8
209.19.85.8/30, version 480, internal 0x5000001 0x0 (ptr 0xa1413cf4) [1], 0x0
(0x0), 0x0 (0x0)
local adjacency 10.12.13.12
  Prefix Len 30, traffic index 0, precedence n/a, priority 4
  via 10.12.13.12, 2 dependencies, recursive, bgp-ext [flags 0x6020]
  path-idx 0 NHID 0x0 [0xa14144f4 0x0]
  next hop 10.12.13.12 via 10.12.13.12/32
```

Fortunately, NAT64 adds this IPv4 pool to the RIB as a static route, so we can simply redistribute it into IS-IS to achieve reachability. From NAT64 perspective, this is critical since returning traffic is directed into the NVI to be translated from v4 to v6. From a routing perspective, it gives us a mechanism to redistribute the NAT64 pool to IPv4 routing protocols. Once complete, the Internet router sees this exact match prefix from XRv1.

```
! CSR8
ip prefix-list PL_PUBLIC seq 5 permit 209.19.85.8/32
```

```
route-map RM_STATIC_TO_ISIS permit 10
  match ip address prefix-list PL_PUBLIC
```

```
router isis 1112
  redistribute static ip route-map RM_STATIC_TO_ISIS
```

```
RP/0/0/CPU0:XRv3#show cef 209.19.85.8/32
209.19.85.8/32, version 486, internal 0x5000001 0x0 (ptr 0xa14147f4) [1], 0x0
(0x0), 0x0 (0x0)
local adjacency 10.11.13.11
  Prefix Len 32, traffic index 0, precedence n/a, priority 4
  via 10.11.13.11, 2 dependencies, recursive, bgp-ext [flags 0x6020]
  path-idx 0 NHID 0x0 [0xa1414574 0x0]
  next hop 10.11.13.11 via 10.11.13.11/32
```

With basic IPv4 routing resolved, we will continue verifying stateful NAT64. Verifying the prefix is similar to stateless NAT64 as it shows the user-defined prefixes as valid and applied to the proper interfaces. Again, we used different interface-level prefixes on the LSN because the downstream clients have different NAT64 stateless prefixes in this example.

```
R8#show nat64 prefix stateful interfaces
Stateful Prefixes
Interface
    NAT64 Enabled Global Prefix
GigabitEthernet2.518
    TRUE                FALSE  3001::/96
GigabitEthernet2.528
    TRUE                FALSE  3002::/32
```

Next, we verify that the pool was configured properly. It consists of exactly 1 useable IPv4 address.

```
R8#show nat64 pools name NAT64_POOL
Protocol HSL ID      Name
    Is Single Range
    Ranges
IPv4      1          NAT64_POOL
    TRUE          (209.19.85.8 - 209.19.85.8)
    209.19.85.8 - 209.19.85.8
```

As a troubleshooting aid when dealing with routing issues, we can see the static routes created by NAT64 for IPv6 prefixes and IPv4 pools using the commands below. A single /32 sufficiently covers the IPv4 pool in this case. An IPv4 pool may require a collection of static routes to cover the entire range. Additionally, each IPv6 prefix causes NAT64 to add a static route to direct traffic into the NVI.

```
R8#show nat64 prefix stateful static-routes
Stateful Prefixes
NAT64 Prefix
    Static Route Ref-Count
3001::/96
    1
3002::/32
    1
```

```
R8#show nat64 pools routes
Pools configured: 1
Protocol HSL ID      Name
    Is Single Range
    Ranges
IPv4      1          NAT64_POOL
    TRUE          (209.19.85.8 - 209.19.85.8)
    209.19.85.8 - 209.19.85.8
```

Static Routes for Range: 1 209.19.85.8/32

Because we know how traffic is being encoded inside IPv6, we can quickly check the IPv6 FIB to ensure return traffic is routed correctly. For CSR2 this is easier since 2222::/16 is not used for anything else. For CSR1, we must ensure the longer-match route was configured correctly. I highlight the embedded IPv4 private source addresses for clarity (192.168.1.14 or 192.168.2.14 for CSR1 and CSR2, respectively).

```
R8#show ipv6 cef 3001::C0A8:10E
3001::C0A8:100/120
  nexthop FE80::1 GigabitEthernet2.518
```

```
R8#show ipv6 cef 2222:0:c0a8:020E::
2222::/16
  nexthop FE80::2 GigabitEthernet2.528
```

To test it, I begin sending large pings from XRv4 towards the Internet. I begin with using CSR2 as the gateway since it is the simpler case. This time, the pings are successful as shown below. With EPC enabled on CSR8, we can see the incoming IPv6 packet from CSR2 and the outgoing IPv4 packet from CSR8. The public IPv4 address of 209.19.85.8 is used as the IPv4 source with a destination of the original IPv4 Internet host. Because CSR8 had a matching IPv6 stateful prefix for CSR2's NAT64 stateless prefix, it knew exactly where to find the IPv4 addresses.

```
R8#show monitor capture CAP buffer detailed
 0 546      0.000000      2222*:0000      -> 3002*:0000      IPv6-Frag
0000: 005056A9 FB1C0050 56A9BE8A 81000DC8      .PV....PV.....
0010: 86DD6000 000001E8 2CFD2222 0000C0A8      ..`.....,..."....

0020: 55080D90 02010800 96620003 0000ABCD      U.....b.....
0030: ABCDABCD ABCDABCD ABCDABCD ABCDABCD      .....
```

Viewing the translation table, the output is somewhat similar to the deprecated NAT-PT feature. There are 4 key pieces of information. The original IPv4 address is the destination that XRv4 was trying to reach initially (Internet host). When this was translated into an IPv6 address, it was wrapped inside the 3002::/32 prefix, which is highlighted. The second row shows the original IPv6 address, which was the source of the traffic entering CSR8. After translations, the post-NAT64 address came from the IPv4 pool and represents CSR8's public address. A simpler way to read this table would be to read it by columns. The IPv4 column shows the destination/source of the post-NAT IPv4 packet (outgoing). The IPv6 column shows that destination/source of the pre-NAT IPv6 packet (incoming). This "shortcut" is confirmed by the EPC capture above.

```
R8#show nat64 translations
```

Proto	Original IPv4	Translated IPv4
	Translated IPv6	Original IPv6
icmp	13.144.2.1:1	[3002:0:d90:201::]:24732
	209.19.85.8:1	[2222:0:c0a8:20e::]:24732

We can check the statistics to confirm that all 5 packets in the ping test succeeded. Gig2.528 translated packets from v6 to v4, while Gig2.582 translated them back from v4 to v6.

```
R8#show nat64 statistics interface gig2.528

```

Quickly backtracking to CSR2 (and clearing the NAT64 statistics for clarity), we can check the v4v6 prefix for translations. It shows that 5 packets were translated in both directions, which suggests connectivity is functional. When we viewed this output before CSR8 was configured, we only saw v4 to v6 translations. Seeing bidirectional translations on the CPE is a good sign that the LSN is functional.

```
R2#clear nat64 statistics
```

```
RP/0/0/CPU0:XRv4#ping vrf 2 13.144.2.1 size 500
```

Type escape sequence to abort.

Sending 5, 500-byte ICMP Echos to 13.144.2.1, timeout is 2 seconds:

!!!!!!

Success rate is 100 percent (5/5), round-trip min/avg/max = 1/57/89 ms

R2#show nat64 statistics prefix stateless v4v6 2222::/32

NAT64 Statistics

2222::/32:

Packets translated (IPv4 -> IPv6)

Stateless: 5

Stateful: 0

MAP-T: 0

Packets translated (IPv6 -> IPv4)

Stateless: 5

Stateful: 0

MAP-T: 0

Packets dropped: 0

When we attempt the same test using CSR1, it fails. We did not trace the detailed routing process for CSR2 since it “just worked”, so for completeness, we will trace it using CSR1 in the forwarding path.

RP/0/0/CPU0:XRv4#ping vrf 1 13.144.2.1 size 500

Type escape sequence to abort.

Sending 5, 500-byte ICMP Echos to 13.144.2.1, timeout is 2 seconds:

.....

Success rate is 0 percent (0/5)

We used EPC earlier to identify that CSR1 is sending traffic to CSR8 with IPv6 source 3001::C0A8:010E (192.168.1.14) and IPv6 destination 3001::0D90:0201 (13.144.2.1). Based on this, CSR8 should be routing this traffic to the NVI. The NAT64-installed static route for the IPv6 stateful prefix 3001::/96 appears to be working.

R8#show ipv6 cef 3001::d90:201

3001::/96

nexthop ::100.0.0.1 NVI0

Once in the NVI, the NAT64 ACL is processed. This particular flow matches sequence 10. Assuming NAT64 worked, CSR8 also has a route to the final destination as well. Without this route, the earlier test using CSR2 would have also failed.

R8#show access-lists ACL_LSN_64

IPv6 access list ACL_LSN_64

permit ipv6 3001::/96 3001::/96 sequence 10

permit ipv6 2222::/32 3002::/32 sequence 20

R8#show ip cef 13.144.2.1

13.0.0.0/8

```
nexthop 10.8.12.12 GigabitEthernet2.582
```

At this point, NAT64 should be occurring, but it isn't. Instead, all 5 of the pings were dropped.

```
R8#show nat64 statistics prefix stateful 3001::/96
NAT64 Statistics
3001::/96:
  Packets translated (IPv4 -> IPv6)
    Stateless: 0
    Stateful: 0
    MAP-T: 0
  Packets translated (IPv6 -> IPv4)
    Stateless: 0
    Stateful: 0
    MAP-T: 0
  Packets dropped: 5
```

Even with all NAT64 debugging enabled, no information is given. I send more pings via XRv4 (no shown) yet we are presented with no debug output, no NAT64 translations, and another 5 dropped packets.

```
R8#debug nat64 all
NAT64 debugging is on
[no output]
```

```
R8#show nat64 translations
Proto  Original IPv4      Translated IPv4
      Translated IPv6  Original IPv6
-----
```

```
Total number of translations: 0
```

```
R8#show nat64 statistics prefix stateful 3001::/96 | include dropped
Packets dropped: 10
```

At this point, the problem is impossible to identify without an educated guess. The only significant difference between CSR1 and CSR2 is that CSR1's source IPv6 address also falls within the NAT64 stateful prefix range. That is to say, when CSR8 tries to perform NAT64 on a specific destination inside the range 3001::/96, it also sees the IPv6 packet's source falls within the same range. I assume that this is the reason NAT64 silently discards these packets as a loop control mechanism. After hours of testing and troubleshooting (absent any formal documentation), I believe this is the reason for the failure. I leave CSR1 broken for reference; if we were going to fix it, we would need to use a separate stateless NAT64 prefix for source and destination as CSR2 does.

We progress to configuring CSR3 and CSR4 with stateless NAT64. They both serve a single client on a LAN so their configurations will be similar. For brevity, I do not show the NAT44 removal and IPv4 cleanup. I also do not show enabling IPv6 or NAT64 on the interfaces as this is very basic. There is

nothing preventing CSR3 and CSR4 from sending traffic to the same IPv6 destination, so the NAT64 v6v4 prefix applied to the dialers can be identical. The v4v6 prefix applied globally, used for IPv6 source addresses, should be different to guarantee optimal routing. The prefix lengths between v6v4 and v4v6 prefixes do not have to match. I create the standard 13.0.0.0/8 route to the NVI for incoming IPv4 traffic, and enable a minor fragmentation option. IPv6 can insert fragmentation headers for fragmented packets, and NAT64 does this automatically. That is why the EPC captures shown earlier displayed “IPv6-Frag” versus “IPv6-ICMP”. This option prevents that fragmentation header from being imposed and I enable it on CSR3 only. The /104 static routes are similar to the one used on CSR1; this directs the IPv6 traffic towards the LSN rather than looping it through the NVI indefinitely.

```
! CSR3
interface Dialer3
  nat64 prefix stateless v6v4 3034:BEEF:2BAD::/96

nat64 prefix stateless v4v6 3034:3::/32
nat64 settings fragmentation header disable
nat64 route 13.0.0.0/8 Dialer3
ipv6 route 3034:BEEF:2BAD:0:0:0:0d00:0/104 Dialer3

! CSR4
interface Dialer4
  nat64 prefix stateless v6v4 3034:BEEF:2BAD::/96

nat64 prefix stateless v4v6 3034:4::/32
nat64 route 13.0.0.0/8 Dialer4
ipv6 route 3034:BEEF:2BAD:0:0:0:0d00:0/104 Dialer4
```

Since HSRP was originally tracking the presence of an IPv4 default route, I remove the tracking mechanism entirely since it is beyond the scope of NAT64 and complicates our test. CSR3 is active for both IPv4 and IPv6 due to having a higher priority.

```
R3#show standby brief
                P indicates configured to preempt.
                |
Interface      Grp   Pri P State   Active          Standby          Virtual IP
Gi2.534        344   105 P Active   local          192.168.34.4    192.168.34.254
Gi2.534        346   105 P Active   local          FE80::4         FE80::254
```

The CSR3 and CSR4 configurations are almost identical, so I only verify CSR3 for brevity. Below, I quickly verify the global v4v6 prefix (sources) and interface-specific v6v4 prefix (destination). CSR4 would show a different v4v6 prefix but the same v6v4 prefix.

```
R3#show nat64 prefix stateless v4v6 global
Global v4v6 Stateless Prefix: is valid, 3034:3::/32
IFs Using Global Prefix
  Gi2.534
```

Di3

```
R3#show nat64 prefix stateless v6v4 interfaces
v6v4 Stateless Prefixes
Interface
NAT64 Enabled Global Prefix
```

```
Dialer3
TRUE FALSE 3034:BEEF:2BAD::/96
```

Using a specific IPv4 Internet host, I confirm that this traffic is forwarded into the NVI so that NAT64 can occur. This static route was installed via the “nat64 route” command.

```
R3#show ip route 13.144.2.1
Routing entry for 13.0.0.0/8
Known via "static", distance 1, metric 0
Routing Descriptor Blocks:
* 0.0.0.1, via NVI0
Route metric is 0, traffic share count is 1
```

After NAT64, the router needs to send traffic upstream to CSR9. The longer-match /104 static routes accomplish this nicely. The same route can be used on both CSR3 and CSR4 since they use a common v6v4 (destination) prefix, as seen in the configuration snippets earlier.

```
R3#show ipv6 route 3034:beef:2bad::/96 longer-prefixes | begin Appl
a - Application
S 3034:BEEF:2BAD::/96 [1/0]
via ::44, NVI0
S 3034:BEEF:2BAD::D00:0/104 [1/0]
via Dialer3, directly connected
```

Using EPC while pinging from XRv4, we can confirm CSR3 is functioning correctly; an IPv4 packet enters and an IPv6 packet exits. The IPv6 source/destination addresses are from different major networks, which is a requirement for stateful NAT64 to work at the LSN. Notice that the IPv6 packet is 546 bytes, which was the same length as the IPv6 packet seen earlier with the fragmentation header. That IPv6 fragmentation header is 8 bytes, as is the PPPoE encapsulation (cyan), which is why the sizes appear the same now. This proves that the IPv6 fragmentation header was removed from the IPv6 packet after NAT64 occurred; if it was not removed, the size would have been 554. We will see this on CSR4 next.

```

I shut down CSR3's client-side LAN interface so that CSR4 becomes the HSRP active router. Using EPC, I perform the same test. Everything is identical except for two details. The IPv6 source address is using the prefix 3034:4::/32 versus 3034:3::/32, and the packet is 8 bytes larger due to the IPv6 fragmentation header being added by NAT64. This header is shown in pink for completeness, but is not examined/discussed in detail. The IPv6 packet is 554 bytes as expected when accounting for this additional header.

```

```

Both CSR3 and CSR4 reported 5 packets translated from IPv4 to IPv6, which is accurate given the quick testing we conducted. This is a good indication that CPE stateless NAT64 is functioning properly in one direction so far. I bring CSR3's LAN interface back up before continuing.

```

R3#show nat64 statistics global | begin Global

  MAP-T: 0

```

CSR9 will perform stateful NAT64 just as CSR8 does. CSR9 has two public addresses available that are not contiguous, so I will create two separate NAT64 rules with different ACLs. This can be used for “port sharing” so that a single public IPv4 “less overloaded” as there are multiple public IPv4 addresses. CSR9’s public loopbacks are completely removed in order to create the NAT pools, and the resulting NVI-generated IPv4 static routes are redistributed into IS-IS. Since two pools are created, two NAT64 rules are required. One rule maps traffic from CSR3 to 209.19.85.9 and the other maps traffic from CSR4 to 209.19.85.11. With this design (assuming CSR3 and CSR4 had some kind of FHRP load sharing scheme, which they don’t currently), each public address on CSR9 is less saturated with ports. Because CSR3 and CSR4 use the same v6v4 (destination) prefix, CSR9 can define a global NAT64 stateful prefix. CSR8 had to use these per-interface since CSR1 and CSR2 used different destination IPv6 addresses. With PPPoE, this would be impossible since there is only a single “interface” towards the CPE routers, so having the PPPoE clients use the same v6v4 (destination) prefix is required. Enabling NAT64 on the virtual-template and upstream transit links is not shown for brevity.

```

! CSR9
ipv6 access-list ACL_NAT_FROM_3
  permit ipv6 3034:3::/32 3034:BEEF:2BAD::/96

ipv6 access-list ACL_NAT_FROM_4
  permit ipv6 3034:4::/32 3034:BEEF:2BAD::/96

nat64 prefix stateful 3034:BEEF:2BAD::/96
nat64 v4 pool NAT64_POOL_11 209.19.85.11 209.19.85.11
nat64 v4 pool NAT64_POOL_9 209.19.85.9 209.19.85.9
nat64 v6v4 list ACL_NAT_FROM_3 pool NAT64_POOL_9 overload
nat64 v6v4 list ACL_NAT_FROM_4 pool NAT64_POOL_11 overload

```

Rather than use static routes on CSR9 for return traffic to 3034::3/96 and 3034:4::/96, we can use an IPv6 IGP; in this case, we use OSPFv3. It is already in place for IPv6 routing to the IPv6 Internet, and the static routes were auto-generated on the CPEs for stateless NAT64. I redistribute these static NVI routes into OSPFv3 on the CPEs, which provides dynamic return paths for CSR9 (the LSN). I use the most specific prefix-list possible to capture both source prefixes to keep the configuration the same.

```

! CSR3 and CSR4
ipv6 prefix-list PL_V4V6 seq 5 permit 3034::/29 ge 32 le 32

```

```
route-map RM_STATIC_TO_OSPF permit 10
  match ipv6 address prefix-list PL_V4V6
```

```
router ospfv3 9
  address-family ipv6 unicast
    redistribute static route-map RM_STATIC_TO_OSPF
```

We confirm that CSR3 and CSR4 properly redistribute these from static into OSPF. CSR9 learns these routes as OSPF external type-2 routes, as expected.

```
R3#show ospfv3 ipv6 rib redistribution
      OSPFv3 9 address-family ipv6 (router-id 192.168.34.3)
3034:3::/32, type 2, metric 20, tag 0, from static
  via ::43, NVI0
```

```
R4#show ospfv3 ipv6 rib redistribution
      OSPFv3 9 address-family ipv6 (router-id 192.168.34.4)
3034:4::/32, type 2, metric 20, tag 0, from static
  via ::43, NVI0
```

```
R9#show ipv6 route 3034::/29 longer-prefixes | begin Appl
  a - Application
OE2 3034:3::/32 [110/20]
    via FE80::3, Virtual-Access2.2
OE2 3034:4::/32 [110/20]
    via FE80::4, Virtual-Access2.1
```

Before testing NAT64, we quickly configure the validate flow inside CSR9. When packets arrive, whether from CSR3 or CSR4, they are directly into the NVI as expected.

```
R9#show ipv6 route 3034:BEEF:2BAD::13.144.2.1
Routing entry for 3034:BEEF:2BAD::/96
  Known via "static", distance 1, metric 0
  Route count is 1/1, share count 0
  Routing paths:
    ::100.0.0.1, NVI0
    Last updated 00:02:45 ago
```

Assuming there is a match against one of the NAT64 ACLs, the traffic is routed to the final IPv4 destination. CSR9 has two ECMP paths for this via XRv1 and XRv2, which is fine.

```
R9#show ip cef 13.144.2.1
13.0.0.0/8
  nexthop 10.9.11.11 GigabitEthernet2.591
  nexthop 10.9.12.12 GigabitEthernet2.592
```

Returning traffic will be destined to either 209.19.85.9 or 209.19.85.11 depending on whether it came from CSR3 or CSR4. In either case, traffic is directed into the NVI as a result of the NAT64 IPv4 pools. The other public addresses are shown below from the other LSNs (learned via IS-IS) but are not relevant for this test. Assuming there was an existing NAT64 translation, traffic would be routed back towards CSR3 or CSR4. This return-flow routing occurs via the OSPFv3 routes we verified earlier.

```
R9#show ip route 209.19.85.8 255.255.255.252 longer-prefixes | begin Gate
Gateway of last resort is not set
    209.19.85.0/32 is subnetted, 4 subnets
i L2      209.19.85.8 [115/20] via 10.9.12.12, 03:28:12, GigabitEthernet2.592
S         209.19.85.9 [1/0] via 100.0.0.2, NVI0
i L2      209.19.85.10 [115/20] via 10.9.11.11, 05:30:58, GigabitEthernet2.591
S         209.19.85.11 [1/0] via 100.0.0.2, NVI0
```

To test it, we use XRv4 again inside VRF 34 which is currently using CSR3 as its default gateway. The pings immediately work, which implies bidirectional connectivity has been achieved.

```
RP/0/0/CPU0:XRv4#ping vrf 34 13.144.2.1 size 500
Type escape sequence to abort.
Sending 5, 500-byte ICMP Echos to 13.144.2.1, timeout is 2 seconds:
!!!!
Success rate is 100 percent (5/5), round-trip min/avg/max = 1/59/89 ms
```

Checking the NAT64 translation table on CSR9, we can see that the original IPv4 packet was destined to 13.144.2.1, an Internet host, and its source was adjusted to be 209.19.85.9. This makes sense since the traffic came from CSR3 (3034:3::/32) and the NAT64 rule specified 209.19.85.9 as the address to use.

```
R9#show nat64 translations
Proto  Original IPv4      Translated IPv4
      Translated IPv6  Original IPv6
-----
icmp    13.144.2.1:1      [3034:beef:2bad::d90:201]:156
        209.19.85.9:1  [3034:3:c0a8:220e::]:156
```

The NAT64 statistics also indicate that 5 packets were translated bidirectionally across CSR9.

```
R9#show nat64 statistics global | begin Global
Global Stats:
    Packets translated (IPv4 -> IPv6)
        Stateless: 0
        Stateful: 5
        MAP-T: 0
    Packets translated (IPv6 -> IPv4)
        Stateless: 0
        Stateful: 5
        MAP-T: 0
```

We can use EPC for additional verification. It does not appear capable of capturing the PPPoE traffic entering the router on the server side (incoming IPv6 packet), so we will limit the verification to the outgoing IPv4 packet. Since ECMP was in play, CSR9 had to decide whether to forward the packet to XRv1 or XRv2. Using show commands, we confirm that XRv2 was selected, and EPC proves it with the destination MAC address in cyan. As usual, I show the source address in yellow (209.19.85.9) and the destination address in green (13.144.2.1).

```
R9#show ip cef exact-route 209.19.85.9 13.144.2.1

```

We expect CSR4 to work identically, except that post-NAT64 address of 209.19.85.11 should be used. Shutting down CSR3's LAN interface, we can force traffic through CSR4. XRv4 can still ping the Internet host (not shown) which means the HSRP failover is functioning as designed. Checking the NAT translations, we see that the other public IPv4 address is used. The statistics also show an additional 5 packets successfully translated, for a total of 10 packets. All of this output is indicative of success so far.

```
R9#show nat64 translations

MAP-T: 0
Packets translated (IPv6 -> IPv4)
Stateless: 0
Stateful: 10
```

MAP-T: 0

Using EPC again, we ensure the packet headers are correct. This time, CSR9 selects XRv1 as the next-hop towards the Internet host since the CEF ECMP function is a combination of both source and destination addresses. Only the source was modified and CEF made a different routing decision. We confirm this decision by checking the destination MAC address in the Ethernet frame. The IPv4 source and destination are in yellow and green, respectively, and represent the correct addresses. Before continuing, CSR3 is brought back online.

```
R9#show ip cef exact-route 209.19.85.11 13.144.2.1

```

Next, we will configure CSR5 for stateless NAT64 in a dual-homed scenario. NAT64 does not currently support route-maps, so the source-based PBR approach cannot be used as it was for NAT444. Instead, we will use destination-based load sharing using the longest-match routing principle with respect to directing traffic into the NVI. Traffic to 13.0.0.0/8 will be sent to CSR9 via Dialer59, but traffic to 13.144.2.24/29 will be sent to CSR10 via Dialer50. You cannot configure multiple NAT64 routes for the same destination in ECMP fashion, but using longest-match to approximate some load sharing is accepted. This could be valuable when a large portion of the upstream traffic flow is directed to subnet 13.144.2.24/29 and it warrants using a separate path for better load distribution. The v4v6 prefix 5000:AAAA::/64 is used for the IPv6 source addressing and there are separate v6v4 (destination) prefixes facing CSR9 and CSR10. Dialer59 uses v6v4 prefix 3034:BEEF:2BAD::/96 just like CSR3 and CSR4, which simplifies the configuration on CSR9. Dialer50 uses v4v6 prefix 3005:DEED:567A::/64 towards CSR10.

```
! CSR5
interface Dialer50
 nat64 prefix stateless v6v4 3005:DEED:567A::/64

interface Dialer59
 nat64 prefix stateless v6v4 3034:BEEF:2BAD::/96

nat64 prefix stateless v4v6 5000:AAAA::/64
```

```

nat64 route 13.0.0.0/8 Dialer59
nat64 route 13.144.2.24/29 Dialer50

```

Before continuing, we verify this configuration. CSR5 has two NAT64-generated static routes to direct traffic towards 13.0.0.0/8 and 13.144.2.24/29 into the NVI. Although not terribly significant, the next-hops are different for each NAT64 route. This differentiation allows NAT64 to know which v6v4 (destination) prefix to use since the “NAT64” route command identified an outgoing interface. The NVIO is a “multi-access network” in this way since a next-hop is specified along with the outgoing interface.

```

R5#show ip route 13.0.0.0 255.0.0.0 longer-prefixes | begin Gate
Gateway of last resort is not set
    13.0.0.0/8 is variably subnetted, 2 subnets, 2 masks
S       13.0.0.0/8 [1/0] via 0.0.0.1, NVIO
S       13.144.2.24/29 [1/0] via 0.0.0.2, NVIO

```

We can see the mapping of IPV4 NAT64 routes to NVIO next-hops using the show command below. This information serves as input to the IPv6 process that generates the static routes.

```

R5#show nat64 routes
IPv4 Prefix      Adj. Address      Enabled Output IF
Global IPv6 Prefix
13.0.0.0/8       0.0.0.1          TRUE      Di59
13.144.2.24/29   0.0.0.2          TRUE      Di50

```

The IPv6 routing is somewhat difficult on CSR5. We need two static IPv6 routes since CSR5 has two uplinks; the masks on these routes “matches” what the NAT64 IPv4 routes were. Dialer59 services traffic inside 13.0.0.0/8, while Dialer50 services traffic inside 13.144.2.24/29. Because each of these uplinks has a different v6v4 (destination) prefix length, the IPv6 routes will differ significantly. Dialer59 is easy since the first 96 bits are the prefix with the last 32 as the IPv4 address. Dialer50’s IPv4 address begins at bit 73 because there are 8 u-bits immediately following the /64 prefix. Because this is complicated, I highlight those bits in pink below. The overall route prefix becomes 64 (prefix) + 8 (u-bits) + 29 (IPv4 mask) = 101. Following the route addition, the v4v6 (source) prefix must be redistributed into OSPFv3; this was required on CSR3 and CSR4 as well. This will allow CSR9 to learn the prefix in order to route returning traffic to CSR5. CSR10 has not yet been configured so we do not expect to have connectivity to 13.144.2.24/29 at this time.

```

! CSR5
ipv6 route 3034:BEEF:2BAD::D00:0/104 Dialer59
ipv6 route 3005:DEED:567A:0:000D:9002:1800:0/101 Dialer50

ipv6 prefix-list PL_V4V6 seq 5 permit 5000:AAAA::/64

route-map RM_STATIC_TO_OSPF permit 10
 match ipv6 address prefix-list PL_V4V6

```

```

router ospfv3 9
 address-family ipv6 unicast
  redistribute static route-map RM_STATIC_TO_OSPF

```

We quickly verify that the redistribution and IPv6 route additions were successful. CSR5 redistributes the v4v6 (source) prefix into OSPFv3 and CSR9 learns it as an OSPF E2 route. The manual static routes remain in CSR5's local IPv6 RIB to forward traffic towards the ISPs.

```
R5#show ospfv3 ipv6 rib redistribution

```

In order for CSR9 to perform NAT64 against traffic from CSR5, we must update CSR9 to account for this new v4v6 (source) prefix 5000:AAAA::/64 that is used by CSR5. CSR9 has two public, post-NAT IPv4 addresses. CSR5 must be configured to use one of them; I simply extend one of the NAT64 ACLs to include CSR5's source prefix. This will cause traffic from CSR5 to use 209.19.85.9 just as CSR3 does.

```

! CSR9
ipv6 access-list ACL_NAT_FROM_3
 sequence 20 permit ipv6 5000:AAAA::/64 3034:BEEF:2BAD::/96

```

There is one minor clean-up we should perform on CSR9 before continuing. Currently, CSR9 is redistributing OSPFv3 into ISIS as this was required for raw IPv6 Internet reachability, beyond the scope of NAT entirely. Because CSR9 is learning NAT64 stateless v4v6 (source) prefixes such as 3034:3::/32, 3034:4::/32, and 5000:AAAA::/64, we should apply a filter to prevent these from leaking to the Internet. Normally these prefixes would be unique local addresses from FC00::/7, but I used public IPv6 prefixes for demonstration. I apply a simple route-map that does not include external routes; only OSPF internal

routes are candidates for redistribution. Checking the local ISIS LSP, we can see that the NAT64 v4v6 (source) prefixes are not included. These PE-CE transit links should never leak to the Internet as their only purpose is to support the NAT64 architecture.

```
! CSR9
route-map RM_OSPF_TO_ISIS_V6 permit 10
  match route-type internal

router isis 1112
  address-family ipv6
    redistribute ospf 9 route-map RM_OSPF_TO_ISIS_V6

R9#show isis database detail R9.00-00 | begin IPv6 Add
IPv6 Address: 2001:10:9:12::9
Metric: 0          IPv6 (MT-IPv6) 2001:192:168:34::/64
Metric: 0          IPv6 (MT-IPv6) 2001:192:168:5::/64
```

To test this new NAT64 configuration, I begin sending pings from XRv4 to 13.144.2.1 which succeed (not shown). This will match the 13.0.0.0/8 NAT64 route on CSR5 and should be sent towards CSR9. Since we have never used a /64 for the source prefix before, I use EPC on CSR5 to see exactly where the IPv4 address is encoded. The source addresses are yellow and the destination addresses are green. The destination IPv4 address is encoded into the v6v4 prefix specified to Dialer59 yet it appears 1 byte (8 bits) after the /64 prefix ends, colored grey. These are the u-bits described earlier, and in this case, they are set to zero. This separates the IPv4 address from the NAT64 v6v4 prefix which makes it a little harder to read, but otherwise has no significance at present. Notice that CSR5 includes the IPv6 fragmentation header since we did not explicitly disable it (pink) as we did on CSR3.

```

Checking CSR9, we can see a stateful translation entry for this ICMP flow. The “Original IPv6” address is the most interesting here since this clearly shows the u-bit offset that EPC reveal above. The IPv4 address is still encoded correctly but it doesn’t “look nice”. Just before the “c0” in this address are two zeroes to represent those u-bits; the router doesn’t show these leading zeroes for brevity. Also notice

that the “Translated IPv6” address is the same post-NAT address used when traffic comes from CSR3 (green); this is the result of modifying the “FROM_3” ACL.

```
R9#show nat64 translations
```

Proto	Original IPv4	Translated IPv4
	Translated IPv6	Original IPv6
icmp	13.144.2.1:1	[3034:beef:2bad::d90:201]:45212
	209.19.85.9:1	[5000:aaaa::c0:a805:e00:0]:45212

CSR5 will not be able to send traffic to 13.144.2.24/29 until CSR10 is configured. We quickly configure CSR10 with a straightforward stateful NAT64 configuration similar to CSR9 and CSR10. In the NAT444 lab, CSR10 was running VRF-lite since NAT44 is VRF-aware. NAT64 is not currently VRF-aware, so all VRFs are removed from CSR10 and only the global table is used (VRF removal and subsequent cleanup not shown). CSR10 will match traffic using the prefixes defined by CSR5’s stateless NAT64 process and map those to its single public IPv4 address of 209.19.85.10. This pool spawns a static route to the NVI and must be redistributed into IS-IS so upstream routers can forward returning traffic back towards the LSN.

```
! CSR10
ipv6 access-list ACL_NAT
 permit ipv6 5000:AAAA::/64 3005:DEED:567A::/64

nat64 v4 pool NAT64_POOL 209.19.85.10 209.19.85.10
nat64 v6v4 list ACL_NAT pool NAT64_POOL overload
nat64 prefix stateful 3005:DEED:567A::/64

ip prefix-list PL_PUBLIC seq 5 permit 209.19.85.10/32

route-map RM_STATIC_TO_ISIS permit 10
 match ip address prefix-list PL_PUBLIC

router isis 1112
 redistribute static ip route-map RM_STATIC_TO_ISIS
```

First, we check to ensure CSR10 creates the IPv4 static route for the NAT64 pool (pointing to the NVI) and redistributes it into IS-IS. This ensures that the Internet routers will have reachability to this post-NAT public address on the LSN.

```

Because there is no good way for CSR10 to configure a static route towards CSR5's v4v6 (source) prefix, I use EIGRPv6 on CSR5 to advertise it dynamically. CSR6, CSR7, and CSR10 were already using EIGRPv6 for this purpose so I extend it to CSR5 as well. It is not directly related to NAT64, but CSR10 must have a route back to 5000:AAAA::/64. Since CSR5 had to redistribute this static route into OSPFv3 for CSR9, the prefix-list/route-map constructs are already in place. EIGRPv6 can simply reuse them even if the route-map name is unintuitive. After the static route is redistributed into EIGRP, we check the topology locally on CSR5 to verify. I also verify that CSR10 learns this is an EIGRP external route, which allows it to send return traffic from the IPv4 Internet back to CSR5. We confirm that the virtual-access interface actually belongs to CSR5 by checking the PPPoE and interface MAC address details.

To protect the IPv6 Internet from these “bogus” v4v6 (source) NAT64 prefixes, I use the same filtering technique on CSR10 as I did on CSR9 except using a prefix-list. The “route-type” matching inside the route-map does not appear to work for EIGRPv6 at this time. This configuration ensures that the NAT64 prefixes are not redistributed from EIGRP into IS-IS.

```

! CSR10

```

At this point, XRv4 should have reachability to 13.144.2.25 which is a host address on the Internet. This traffic should be routed via CSR10. The source will be changed mapped into v4v6 prefix 5000:AAAA::/64 and the destination will be mapped into v6v4 prefix 3005:DEED:567A::/64 associated with Dialer50. CEF directs traffic for 13.144.2.24/20 to the NVI using address 0.0.0.2, which is tied to Dialer50.

```

```

After NAT64 occurs, the destination IPv6 address will fit within a relatively specific route which routes traffic towards the IPv4 prefix 13.144.2.24/29 towards Dialer50. Without this route, traffic would loop back into the NVI and be dropped. These are the static routes we verified earlier but are shown again for completeness.

```

R5#show ipv6 route 3005:DEED:567A::/64 longer-prefixes | begin Appl
    a - Application
S   3005:DEED:567A::/64 [1/0]

S   3005:DEED:567A:0:D:9002:1800:0/101 [1/0]
    via Dialer50, directly connected

```

Using EPC on CSR5, we can see the incoming LAN IPv4 and outgoing WAN IPv6 packet. Both the IPv6 source and destination include the u-bits, shown in grey, since their prefix lengths are shorter than /96. Even the /32 prefixes included the u-bits, but it was less significant since the IPv4 addresses were encoded first. If the prefix length is less than or equal to 64, the u-bits will always exist. If they exist, u-bits are always in the same place as described earlier. Source addresses are shown in yellow with destination addresses in green, as usual. For consistency, the PPPoE encapsulation is shown in cyan and the IPv6 fragmentation header is shown in pink, but neither one is relevant to this discussion.

```

```

CSR10 will receive packets towards 3005:DEED:567A:0:D:9002:1900:0 which was the destination seen in the EPC above. This is the “Translated IPv4” address from CSR10’s perspective seen below. The public IPv4 address used comes from the NAT v4 pool and is 209.19.85.10, which is redistributed into ISIS. XRv4 can now reach all Internet hosts using both CSR9 and CSR10.

```

R10#show nat64 translations
Proto  Original IPv4      Translated IPv4
      Translated IPv6  Original IPv6
-----
icmp    13.144.2.25:1      [3005:deed:567a:0:d:9002:1900:0]:57500
        209.19.85.10:1  [5000:aaaa::c0:a805:e00:0]:57500

```

Assuming that CSR6 is not capable of stateless NAT64, we can use stateful NAT64 with static mappings. Although this does not support address overloading, it does allow us to specify direct mappings between IPv4 and IPv6 addresses. When traffic enters CSR6 destined to 13.144.2.1, CSR6 will encode the destination inside of the already-supported destination prefix 3005:DEED:567A::/64. We manually have to determine the correct destination IPv6 address because CSR10 will care. CSR10 is already expecting traffic for this stateful prefix as it supports CSR5. We have to expand CSR10’s NAT ACL to account for a new source, CSR6, as well as advertise this new source into EIGRP.

```

! CSR6
nat64 prefix stateful 6006:FEED:BEAD::/96
nat64 v6v4 static 3005:DEED:567A:0:D:9002:100:0 13.144.2.1

```

We will expand the NAT ACL to include the new source, and adjust the EIGRP-to-ISIS redistribution to prevent this “bogus” route from polluting the IPv6 Internet. This is the same procedure we configured earlier so that CSR10 could support CSR5. I show the full PL and ACL configuration for completeness; there is one line for each supported CPE router at this point. CSR10’s logic hardly changes. After updating the NAT ACL, traffic from 6006:FEED:BEAD::/96 will be candidate for NAT using 209.19.85.10 as the post-NAT public address. In this way, both the CPE and LSN are technically using stateful NAT64.

```
! CSR10
ipv6 prefix-list PL_V4V6 seq 5 permit 5000:AAAA::/64
ipv6 prefix-list PL_V4V6 seq 10 permit 6006:FEED:BEAD::/96

ipv6 access-list ACL_NAT
  permit ipv6 5000:AAAA::/64 3005:DEED:567A::/64
  permit ipv6 6006:FEED:BEAD::/96 3005:DEED:567A::/64
```

When traffic enters CSR6 towards 13.144.2.1, it is directed to the NVI via a static route. This was installed by NAT64 when the static mapping was added. The route is a /32 host route so no other Internet destinations are included.

```
R6#show ip cef 13.144.2.1
13.144.2.1/32
  nexthop 100.0.0.1 NVI0
```

After NAT64 occurs, the resulting IPv6 packet is forwarded to CSR10 by following the default route. This route was originated by CSR10 inside EIGRPv6 from the last lab, and CSR6 will rely on it here. Unlike stateless NAT64, there is no static NVI route created for this destination IPv6 address; there is no concept of a v4v6 (source) prefix with static mappings. The source address used comes from the stateful NAT prefix 6006:FEED:BEAD::/96 defined above. CSR6 does install a static route for this prefix since the returning traffic must be directed into the NVI for translation back to IPv4.

```
R6#show ipv6 cef 3005:DEED:567A:0:D:9002:100:0
::/0
  nexthop FE80::21E:14FF:FE6F:8300 Dialer6
```

```
R6#show ipv6 route 6006:FEED:BEAD::/96

  Known via "static", distance 1, metric 0
  Redistributing via eigrp 10
  Route count is 1/1, share count 0
  Routing paths:
    ::100.0.0.1, NVI0
    Last updated 00:19:27 ago
```

Since CSR6 has a static, stateful mapping. This will appear in the NAT64 translation table when no traffic is flowing. This behavior is consistent with NAT44 as this static entry works in either direction. These are both effectively “destination” addresses when examined from an upstream traffic flow perspective. Traffic to 13.144.2.1 has its destination changed to the “Original IPv6” address and its source changed to the NAT64 stateful prefix encoded with the original IPv4 source address (which varies).

```
R6#show nat64 translations
Proto Original IPv4      Translated IPv4
      Translated IPv6    Original IPv6
-----
---      ---      ---
      13.144.2.1      3005:deed:567a:0:d:9002:100:0
```

When XRv4 sends traffic to 13.144.2.1, CSR6 translates it as shown below. The “Original IPv4” address is the original source, which is XRv4. This is encoded into the last 32 bits of the NAT64 /96 stateful prefix as examined many times thus far. The “destination” IPv4/IPv6 addresses are fixed and do not change, with the exception of a port number used for demultiplexing.

```
R6#show nat64 translations
```

Proto	Original IPv4	Translated IPv4
	Translated IPv6	Original IPv6
---	---	---
	13.144.2.1	3005:deed:567a:0:d:9002:100:0
icmp	192.168.6.14:12444	[6006:feed:bead::c0a8:60e]:12444
	13.144.2.1:12444	[3005:deed:567a:0:d:9002:100:0]:12444

Checking CSR10, NAT64 is performed based on traffic entering the router with a destination inside the stateful NAT64 prefix of 3005:DEED:567A::/64. Because CSR6 manually formatted this correctly in the static NAT64 mapping, CSR10 is able to perform dynamic NAT64 by extracting the original IPv4 destination address of 13.144.2.1. The “Original IPv6” address, which carries to the encoded IPv4 original source, doesn’t get decoded again. It is only used for mapping returning flows destined to 209.19.85.10 back to the proper downstream customer.

```
R10#show nat64 translations
```

Proto	Original IPv4	Translated IPv4
	Translated IPv6	Original IPv6
---	---	---
icmp	13.144.2.1:1	[3005:deed:567a:0:d:9002:100:0]:16540
	209.19.85.10:1	[6006:feed:bead::c0a8:60e]:16540

Quickly checking CSR6’s NAT64 statistics, we can see packets being translated bidirectionally on the proper interfaces.

```
R6#show nat64 statistics interface gig2.564

```

With this static NAT64 architecture in place, accessing new Internet hosts is simple. To access XRv3's remaining 3 interfaces, we simply need to add a static mappings for each. We manually determine the post-NAT IPv6 destination address so that CSR10 can correctly decode the embedded IPv4 address. From XRv4, I ping all 4 destinations and examine the translation table. All of the pings succeed.

```

On CSR7, I demonstrate using the well-known prefix (WKP) for stateful NAT64. The WKP prefix is 64:FF9B::/96 and cannot be disabled. Any router with NAT64 enabled, even stateless NAT64, will have a static route directing traffic to this destination into the NVI. CSR7 will use this as the destination IPv6 prefix as CSR10 will automatically direct this into its NVI without us having to configure it. The NAT64 manually-specified prefix configured on CSR7 will be used as the source address when NAT64 generates IPv6 packets. The basic NVI static route redistribution into EIGRP is shown again which is similar to CSR6.

```

! CSR7
nat64 prefix stateful 7007:FEED:BEAD::/96
nat64 v6v4 static 64:FF9B::D90:201 13.144.2.1

ipv6 prefix-list PL_V4V6 seq 5 permit 7007:FEED:BEAD::/96

route-map RM_STATIC_TO_EIGRP permit 10
 match ipv6 address prefix-list PL_V4V6

```

```

router eigrp LSN
 address-family ipv6 unicast autonomous-system 10
 topology base
 redistribute static route-map RM_STATIC_TO_EIGRP

```

CSR7 must define a longer-match static route to ensure traffic towards this destination isn't looped into its local NVI. Since CSR7 is running NAT64 also, we need to totally ignore the 64:FF9B::/96 prefix from a routing perspective. A /97 is not very specific, but it's good enough for this test case.

```

! CSR7
ipv6 route 64:FF9B::/97 Dialer7

R7#show ipv6 route 64:FF9b::/96 longer-prefixes | begin Appl
  a - Application
S   64:FF9B::/96 [1/0]
    via ::100.0.0.2, NVI0
S   64:FF9B::/97 [1/0]
    via Dialer7, directly connected

```

CSR10 must expand its list of "bogus" IPv6 prefixes to filter from ISIS, along with its NAT ACL. The NAT ACL now matches traffic from CSR7 towards the WKP. Notice that CSR10 does not have to define a new NAT64 prefix, since 64:FF9B::/96 is automatically created. The IPv6 static route for the WKP towards the NVI is automatically generated as soon as NAT64 is enabled as we saw on CSR7 also.

```

! CSR10
ipv6 prefix-list PL_V4V6 seq 5 permit 5000:AAAA::/64
ipv6 prefix-list PL_V4V6 seq 10 permit 6006:FEED:BEAD::/96

```

On CSR7, we can see the new static translation. Tracing the routing logic, incoming IPv4 packets to 13.144.2.1 are sent to the NVI. Outgoing IPv6 packets match the /97 route via Dialer7 towards CSR10. We verified CSR10's route to the Internet earlier, as well as its local WKP route to the NVI for incoming IPv6 packets.

```

```

R7#show ipv6 cef 64:ff9b::d90:201
64:FF9B::/97
  attached to Dialer7

```

Just like CSR6, this works without issue. CSR7 translates private IPv4 into transitory IPv6, then CSR10 translates transitory IPv6 into public IPv4. I highlight the private and public IPv4 source addresses, which

is the primary use-case of NAT464 for LSN in general. I don't verify all the statistics again since this logic is identical to CSR6 except uses the WKP.

```
R7#show nat64 translations
```

	13.144.2.1:45212	[64:ff9b::d90:201]:45212

```
R10#show nat64 translations
```

Proto	Original IPv4	Translated IPv4
	Translated IPv6	Original IPv6
---	---	---
icmp	13.144.2.1:1	[64:ff9b::d90:201]:45212
	209.19.85.10:1	[7007:feed:bead::c0a8:70e]:45212

Rather than enumerate the remaining Internet mappings on CSR7 as we did on CSR6, we will use TCP/UDP specific mappings for variety. Starting with TCP, we create a mapping for telnet. This will give XRv4 telnet access to XRv3, but nothing else. Because I use port 23 for both the IPv4 and IPv6 components, the number is effectively passed through. This allows CSR10 to maintain the destination port 23 when it performs NAT64-overload. I use IPv4 address 13.144.2.9 on XRv3 for variety.

```
! CSR7
```

```
nat64 v6v4 static tcp 64:FF9B::D90:209 23 13.144.2.9 23
```

```
R7#show nat64 translations protocol tcp
```

Proto	Original IPv4	Translated IPv4
	Translated IPv6	Original IPv6
---	---	---
tcp	13.144.2.9:23	[64:ff9b::d90:209]:23

When the telnet flow begins, CSR7 creates a new state entry for the specific flow, which includes the source IPv4 address and source port. The source port is carried over exactly (cannot be modified), but the destination port is treated the same due to our configuration. The flow appears to be coming from CSR7 towards the WKP destination shown below.

```
R7#show nat64 translations protocol tcp
```

Proto	Original IPv4	Translated IPv4
	Translated IPv6	Original IPv6
---	---	---
tcp	13.144.2.9:23	[64:ff9b::d90:209]:23

```

tcp      192.168.7.14:29960    [7007:feed:bead::c0a8:70e]:29960
        13.144.2.9:23    [64:ff9b::d90:209]:23

```

This WKP destination is routed to CS10's NVI. The IPv4 address is decoded from the packet and the TCP port number is maintained. Due to overloading, the original source port is rewritten to some demultiplexing value that CSR10 selects; it is 1015 in this case. The final IPv4 packet is highlighted. XRv3 correctly acknowledges this as a telnet session from 209.19.85.10 using port 1025 as shown in its TCP table.

```

R10#show nat64 translations protocol tcp

    Packets translated (IPv6 -> IPv4)
      Stateless: 0
      Stateful: 0
      MAP-T: 0
    Packets dropped: 8

```

Next, we will perform the same test with UDP. Using IP SLA, we will create a probe using port 42518 towards 13.144.2.17. IP SLA might be useful to test a custom application across NAT64 devices to an Internet destination. The IP SLA configuration on XRv3 and XRv4 is very basic; the details are described

in the IP SLA section. XRv3 is configured to respond to 13.144.2.17:42518 and XRv4 is configured to send traffic to that address/port pair.

```
! XRv3
ipsla
 responder
  type udp ipv4 address 13.144.2.17 port 42518

! XRv4
ipsla
 operation 7
  type udp echo
  vrf 7
  destination address 13.144.2.17
  control disable
  timeout 3000
  destination port 42518
  frequency 5

schedule operation 7
 start-time now
 life forever
```

On CSR7, we use the same logic as we did for TCP. The port number 42518 is maintained across the NAT64 process; otherwise, the configuration is identical.

```
! CSR7
nat64 v6v4 static udp 64:FF9B::D90:211 42518 13.144.2.17 42518
```

Checking the translations on CSR7 and CSR10, we can see the IP SLA probe. XRv4 is using source port 35760 which is transparent across the static NAT64 mapping. The destination port is also transparent due to the configuration. CSR10 adjusts the source port since it is overloading a single IP address, but otherwise the logic is similar. Port 42518 is ultimately revealed to XRv3 who can respond correctly.

```
R7#show nat64 translations protocol udp
Proto  Original IPv4      Translated IPv4
      Translated IPv6  Original IPv6
-----
udp    ---
      13.144.2.17:42518  [64:ff9b::d90:211]:42518
udp    192.168.7.14:35760  [7007:feed:bead::c0a8:70e]:35760
      13.144.2.17:42518  [64:ff9b::d90:211]:42518

R10#show nat64 translations protocol udp
Proto  Original IPv4      Translated IPv4
      Translated IPv6  Original IPv6
-----
```

```
udp      13.144.2.17:42518      [64:ff9b::d90:211]:42518
        209.19.85.10:1024      [7007:feed:bead::c0a8:70e]:35760
```

To ensure it is working, we check the IP SLA statistics on XRv4. The probe is succeeding and there is bidirectional reachability for this new “custom application”.

```
RP/0/0/CPU0:XRv4#show ipsla statistics 7 | utility egrep 'Number|return'
Number of operations attempted: 74
Number of operations skipped   : 0
Latest operation return code   : OK
```

Last, I demonstrate changes the destination port. This can mask the user from the actual ports used by the target. For example, to access 13.144.2.25 via telnet, the user (XRv4) must use port 2300 rather than 23.

```
! CSR7
nat64 v6v4 static tcp 64:FF9B::D90:219 23 13.144.2.25 2300
```

```
R7#show nat64 translations v6 translated 13.144.2.25
```

Proto	Original IPv4	Translated IPv4
	Translated IPv6	Original IPv6

tcp	---	---
	13.144.2.25:2300	[64:ff9b::d90:219]:23

The logic is identical to the original telnet test, except XRv4 specifies port 2300 now. CSR7 translates this to destination port 23; CSR10 remains unaware of any changes.

```
R7#show nat64 translations v6 translated 13.144.2.25
```

Proto	Original IPv4	Translated IPv4
	Translated IPv6	Original IPv6

tcp	---	---
	13.144.2.25:2300	[64:ff9b::d90:219]:23

	13.144.2.25:2300	[64:ff9b::d90:219]:23

Additional Reading – Reference configurations "Isn-464"

36.3 Dual stack lite (DS-lite)

DS-Lite takes the advantages of NAT464 and simplifies the deployment concept. Because NAT64 may not be supported on low-end CPE routers in residential deployments, DS-Lite is an alternative that allows IPv4 to be encapsulated inside IPv6. Just like the NAT464 model, the CPE-to-LSN links are still IPv6, but the redundancy, performance, and scaling concerns are eliminated since translation is no

longer occurring at the CPE. IPv4 traffic tunneled to the LSN inside IPv6 is decapsulated, and then regular NAT44 is performed.

When coupled with NAT44, however, DS-Lite adds a key piece of information. Because NAT44 was not performed on the CPEs, it is possible that the same private addressing could be used by multiple CPEs beneath a single LSN. With NAT444, this is not a concern since the SP-allocated private addressing, which is the outside address for the CPE, would be unique at each CPE. With DS-Lite, no such concept exists. The NAT44 process, when interacting with DS-Lite, adds the source IPv6 address of the DS-Lite tunnel to the NAT state. This mapping provides a destination address for return traffic entering the LSN from the outside, as well as differentiates CPE private addressing. Like with NAT444 and NAT464, native IPv6 traffic is routed normally with no additional encapsulation or NAT applied.

This feature is not currently supported on IOS, IOS-XE, or XRv. It is supported on IOS-XR platforms but only with specific hardware enhancements. Specifically, The ASR9000 series Integrated Service Module (ISM) for CGN and the CRS Carrier Grade Services Engine (CGSE). A sample configuration from Cisco is shown below, though it cannot be demonstrated on XRv.

36.4 IPv6 tunneling over IPv4 networks

There are many techniques for connecting isolated IPv6 networks over IPv4 transport. Several methods are tested below, and they all share a common network diagram. Each subsection is independent from the others but all rely on the same MPLS network providing L3VPN service for IPv4 only. The MPLS configurations are very basic with XRv1 as a VPNv4 RR and all LSRs running LDP. The PE-CE routing protocol is nonexistent as, like the LISP lab, the PEs just redistribute the connected transit link into BGP and the CEs have a static default IPv4 route pointing towards the PEs. Routers are color-coded in the diagram below to show which tunneling techniques they will use. The focus is on 6RD since the other mechanisms are less applicable to service providers, but are valid IPv6 transition options nonetheless.

Below is a comparison of different IPv6 tunneling techniques. Some techniques are clearly better than others based on the natural progression of time (e.g., 6RD is a newer variant of 6to4), but each of them has valid use cases. Legacy auto-tunnels are not examined here at all. One thing that all tunnels have in common is they require an IPv4 source address, which is omitted from the chart for brevity.

Protocol/Method	Uses	Notes
Manual IPv6-in-IPv4	P2P tunnel, intra or inter site, manually configured	Carries IPv6 only, can run IGP and BGP
GRE	P2P tunnel, intra or inter site, manually configured	Carries IPv4, IPv6, CLNS, etc. but adds extra 4-byte encapsulation, can run IGP and BGP
6to4	P2MP tunnel, inter site, automatic based on IPv4 address	Limited to 2002::/16 prefix, inflexible prefix format, anycast-based relay for Internet access using specific addresses
6RD	P2MP tunnel, inter site, automatic based on IPv4 address	Flexible prefix format, simplified relay mechanism, can use SPs own address space
ISATAP	P2MP tunnel, intra site, automatic based on IPv4 address	Can run IGPs (unicast neighbors) and BGP

Additional Reading - Reference configurations "ipv6-tunnels"

36.4.1 GRE / Manual IPv6 tunnels

The simplest method to bridge disparate IPv6 islands is to create a GRE tunnel between sites and run IPv6 inside of it. This is also supported with DMVPN and any other GRE-based technology. XR also supports this method, but none of the others (at least not without special hardware modules). CSR6 and XRv4 form this basic GRE tunnel between one another. The tunnel endpoints have reachability through the L3VPN via IPv4 using default routes. There are no tunnel IPv4 addresses since the customer sites are IPv6 only.

```
! CSR6
interface GigabitEthernet2.546
 encapsulation dot1Q 3546
 ip address 10.4.6.6 255.255.255.0

ip route 0.0.0.0 0.0.0.0 10.4.6.4

interface Tunnel614
 description BASIC GRE
 ipv6 address FE80::6 link-local
 ipv6 address FD00:10:6:14::6/64
 tunnel source 10.4.6.6
 tunnel destination 10.2.14.14

! XRv4
interface GigabitEthernet0/0/0/0.524
 ipv4 address 10.2.14.14 255.255.255.0
 encapsulation dot1q 3524

router static
 address-family ipv4 unicast
 0.0.0.0/0 10.2.14.2
```

```

interface tunnel-ip614
  description BASIC GRE
  ipv6 address fe80::14 link-local
  ipv6 address fd00:10:6:14::14/64
  tunnel source 10.2.14.14
  tunnel destination 10.4.6.6

```

A quick verification on each router shows that the traffic is carried inside IPv4 between the tunnel source and destination. This is nothing new as we tested this in the GRE section as well.

```

R6#show interfaces tunnel614 | include Tunnel
Tunnel614 is up, line protocol is up
  Hardware is Tunnel
  Tunnel linestate evaluation up
  Tunnel source 10.4.6.6, destination 10.2.14.14
  Tunnel protocol/transport GRE/IP
  Tunnel TTL 255, Fast tunneling enabled
  Tunnel transport MTU 1476 bytes
  Tunnel transmit bandwidth 8000 (kbps)
  Tunnel receive bandwidth 8000 (kbps)

```

```

RP/0/0/CPU0:XRv4#show interfaces tunnel-ip614 | include Tunnel
  Hardware is Tunnel
  Tunnel TOS 0
  Tunnel mode GRE IPv4,
  Tunnel source 10.2.14.14, destination 10.4.6.6
  Tunnel TTL 255

```

There is no complexity to the BGP configuration either. The snippets are shown below. Dynamic routing is one of the benefits of GRE tunneling that is not supported in 6to4 or 6RD, although one could argue that it isn't necessary for those models in the first place.

```

! CSR6
router bgp 614
  no bgp default ipv4-unicast
  neighbor FD00:10:6:14::14 remote-as 614
  address-family ipv6
    network ::10:6:6:6/128
  neighbor FD00:10:6:14::14 activate

! XRv4
router bgp 614
  address-family ipv6 unicast
    network ::10:14:14:14/128

  neighbor fd00:10:6:14::6
    remote-as 614
  address-family ipv6 unicast

```

From CSR6, we can verify the BGP session is up then check to ensure CSR6 learns XRv4's loopback. We also quickly test reachability.

```
R6#show bgp ipv6 unicast summary | begin ^Neighbor
Neighbor      V      AS MsgRcvd MsgSent  TblVer  InQ  OutQ Up/Down  State/PfxRcd
FD00:10:6:14::14
              4      14      22      23      3    0    0 00:18:10      1
```

```
R6#show bgp ipv6 unicast | begin Network
      Network      Next Hop      Metric LocPrf Weight Path
*>  ::10:6:6:6/128  ::              0          32768 i
*>i  ::10:14:14:14/128
                                FD00:10:6:14::14
                                0      100      0 i
```

```
R6#ping ::10:14:14:14 source ::10:6:6:6
Type escape sequence to abort.
Sending 5, 100-byte ICMP Echos to ::10:14:14:14, timeout is 2 seconds:
Packet sent with a source address of ::10:6:6:6
!!!!!!
Success rate is 100 percent (5/5), round-trip min/avg/max = 5/11/33 ms
```

As a final data-plane check, we capture packets inbound on CSR2 (PE) to see IPv6 packets encapsulated inside GRE. Notice that the GRE header indicates that the tunneled protocol is IPv6 using 0x86DD. The IPv4 and IPv6 source addresses are highlighted in yellow, where the IPv4 comes first and is the outer encapsulation. IPv4 and IPv6 destination addresses are in green and represent CSR6's address. The GRE header is in pink which clearly shows the IPv6 protocol type. Notice that the IPv4 IP protocol is 47 (0x2F, colored cyan) which is regular GRE; there is nothing special for IPv6 in the outer IP header since the GRE header shows the tunneled protocol.

```
R2#show monitor capture CAP buffer dump
0

```

Manual tunneling is not examined here because it is very simple and almost identical to GRE. The difference is that the tunnel mode is changed to "ipv6ip" with no additional options like 6to4 or 6RD. This is similar to "ip-in-ip" tunneling, IP protocol 4, which is slightly less overhead than GRE but can only carry IPv4 inside IPv4. IPv6-in-IPv4 is the same concept, so non-IPv6 traffic cannot be tunneled inside. IPv6-in-IPv4 uses IP protocol 41 and is shared by 6to4 and 6RD we will see soon. The downside of these approaches (both GRE and manual) is that they are labor-intensive and difficult to deploy large scale.

36.4.2 6to4 automatic tunnels

6to4 tunnels are a fast way to deploy IPv6 tunnels automatically (and without storing state) throughout the network. Somewhat similar to DMVPN, no tunnel destination is specified. Since the IPv6 addresses are so large and can easily encompass IPv4 addresses, the IPv4 tunnel endpoints are embedded inside of the IPv6 addresses. The 6to4 prefix header always begins with 2002::/16 as this prefix was allocated by IANA specifically for 6to4 tunneling. The next 32 bits represent the local IPv4 address for a given site converted to hexadecimal. If the tunnel source was 10.4.6.6 as tested earlier, the 6to4 prefix for that site would be 2002:0A04:0606::/48, which leaves a 16-bit subnet ID as is normally expected for IPv6. This implies that all IPv6 networks local to that site must be encompassed within 2002:0A04:0606::/48, since any remote nodes sending traffic to this prefix automatically know to encapsulate the IPv6 packet into an IPv4 packet destined for 10.4.6.6. CSR3, CSR9, and CSR10 are used for this test. First, we will configure it the “hard way” on CSR9 and CSR10 which does not use the general-prefix construct. The tunnel mode is changed to IPv6-in-IPv4 (protocol 41) with the special “6to4” option. This means that the tunnel does not need an explicit destination as it is embedded inside the IPv6 prefix. Also notice that we don’t need to configure global addressing on the tunnel itself. CSR9 and CSR10 have LAN simulations on loopback0 which are subnets within the /48 prefix specific to each site; you cannot deviate from this, but you do have 65536 subnets of size /64 to allocate, which is a good solution in my opinion.

```
! CSR9
interface Tunnel3910
  description 6TO4
  ipv6 address FE80::9 link-local
  tunnel source 10.9.11.9
  tunnel mode ipv6ip 6to4

interface Loopback0
  ipv6 address 2002:A09:B09:9998::9/128
  ipv6 address 2002:A09:B09:9999::9/128

ipv6 route 2002::/16 Tunnel3910

! CSR10
interface Tunnel3910
  description 6TO4
  ipv6 address FE80::10 link-local
  tunnel source 10.10.13.10
  tunnel mode ipv6ip 6to4

interface Loopback0
  ipv6 address 2002:A0A:D0A:AAAA::A/128
  ipv6 address 2002:A0A:D0A:AAAB::A/128

ipv6 route 2002::/16 Tunnel3910
```

Since CSR9 and CSR10 have almost identical configurations, we limit our verification to CSR9 for brevity. Despite not having a destination, the tunnel comes up. This is a result of 6to4 being enabled which is a multipoint tunnel, similar to DMVPN. The source address is the PE-CE link address which has connectivity with MPLS L3VPN. Notice that MTU is 1480 bytes as opposed to the more commonly seen 1476 with GRE tunnels. Since the IPv6 packet is wrapped inside of a standard 20-byte IPv4 header with no 4-byte GRE encapsulation, the MTU is automatically optimized to the maximum possible value (1500 – 20).

```
R9#show interfaces tunnel3910 | include Tunnel
Tunnel3910 is up, line protocol is up
  Hardware is Tunnel
  Tunnel linestate evaluation up
  Tunnel source 10.9.11.9
  Tunnel protocol/transport IPv6 6to4
  Tunnel TTL 255
  Tunnel transport MTU 1480 bytes
  Tunnel transmit bandwidth 8000 (kbps)
  Tunnel receive bandwidth 8000 (kbps)
```

If we want to send traffic to CSR10, we follow the highly generic 2002::/16 route which directs traffic out of the tunnel. Looking at the IPv6 CEF table, we can see an interesting action in the output chain. After identifying Tunnel3910 as the outgoing interface, another lookup is performed in the IPv4 table. This lookup is based on the embedded IPv4 address for CSR10's tunnel so that the router knows how to ultimately encapsulate the packet inside IPv4, then add the appropriate layer 2 encapsulation.

```
R9#show ipv6 route 2002::/16
Routing entry for 2002::/16
  Known via "static", distance 1, metric 0
  Route count is 1/1, share count 0
  Routing paths:
    directly connected via Tunnel3910
    Last updated 02:05:41 ago

R9#show ipv6 cef 2002::/16 internal | begin output
output chain:
  IPV6 midchain out of Tunnel3910, addr :: 7F3DE5349238
  Lookup in table IPv4:Default
```

Additional details in the adjacency table reveal this as well. We can also confirm the IP protocol number of 41 this way. Notice that the destination IPv4 address in the encapsulation string is all zeroes and the comment mentions that it must “copy from payload”, which is accurate (yellow) The tunnel source IPv4 address is shown just before it and is colored green.

```
R9#show adjacency tunnel3910 :: encapsulation
Protocol Interface Address
```

```

IPV6      Tunnel3910      ::(7)
  Encap length 20

    src: static, 10.9.11.9
    prot: static, 41
    ttl: static, 255
    df: static, cleared
  per packet fields: dst tos ident tl chksum

```

As a safety mechanism, it is good practice (but technically not required for connectivity) to ensure that traffic assigned to a site is not allowed to be sent from that site into the 6to4 network. For example, CSR9 owns the aggregate prefix 2002:A09:B09::/48. If a host behind CSR9 sends traffic to a subnet of this prefix for which CSR9 does not have a longer match, it will try to send it of the 6to4 tunnel. Although the packet won't actually go anywhere since the destination is local, it is sloppy and could introduce a control-plane DoS attack.

```

R9#show ipv6 cef 2002:A09:B09:1:2:3:4:5
2002::/16
  attached to Tunnel3910

```

We can correct this easily with null routes on CSR9 and CSR10. It is still sufficiently generic enough such that longer matches won't get blackholed, but specific enough to override the 2002::/16 for local traffic.

```

! CSR9
ipv6 route 2002:A09:B09::/48 null0

```

```

! CSR10
ipv6 route 2002:A0A:D0A::/48 null0

```

```

R9#show ipv6 cef 2002:A09:B09:1:2:3:4:5
2002:A09:B09::/48
  attached to Null0

```

```

R10#show ipv6 cef 2002:A0A:D0A:1:2:3:4:5
2002:A0A:D0A::/48
  attached to Null0

```

We can test connectivity across the 6to4 tunnel while using EPC outbound on CSR9 at the same time. We will initiate the ping from CSR10 so that we capture CSR9's echo-replies. I also highlight the IPv4 addresses embedded in the IPv6 prefix for clarity; it shows packets going from 10.10.13.10 to 10.9.11.9, which is correct.

```
R10#ping 2002:A09:B09:9998::9 source 2002:A0A:D0A:AAAA::A
Type escape sequence to abort.
Sending 5, 100-byte ICMP Echos to 2002:A09:B09:9998::9, timeout is 2 seconds:
Packet sent with a source address of 2002:A0A:D0A:AAAA::A
!!!!
Success rate is 100 percent (5/5), round-trip min/avg/max = 1/8/22 ms
```

EPC dumps on CSR9 show the entire packet. Unlike the GRE tunnel we saw earlier, the IP protocol is now 41 (0x29) which indicates IPv6-in-IPv4 encapsulation, shown in cyan. As a result, there is no GRE header, which saves 4 bytes of encapsulation (but makes IPv6 the only possible payload protocol). The IPv4 and IPv6 source addresses are shown in yellow again, which is nothing different than before. Likewise, the IPv4 and IPv6 destination addresses are shown in green, which is also similar to the GRE example. In summary, IPv6 traffic flows from CSR9 to CSR10 inside IPv4.

```
R9#show monitor capture CAP buffer dump
0
0000: 005056A9 9C600050 56A9D672 81000E07 .PV..`.PV..r....

0040: 0A0A0D0A AAAA0000 00000000 000A8100 .....
0050: 26C01AA2 00000001 02030405 06070809 &.....
```

Next, we will bring CSR3 into the 6to4 network. We will use the general-prefix construct to simplify the configuration of LAN networks at the CSR3 site. The special “6to4” option is used with the general-prefix and the tunnel source is specified. This auto-computes the 6to4 addressing so you don’t have to do it manually. Notice the odd-looking addresses under loopback0; when referencing a general-prefix, the “::” identifier means that the starting bits of the prefix are copied from the general-prefix. In this case, we specify the last 80 bits of the address since the first 48 come from the general-prefix.

```
! CSR3
ipv6 general-prefix GP_6TO4 6to4 GigabitEthernet2.534

interface Tunnel3910
description 6TO4
ipv6 address FE80::3 link-local
tunnel source GigabitEthernet2.534
tunnel mode ipv6ip 6to4

interface Loopback0
ipv6 address GP_6TO4 ::3333:0:0:0:3/128
ipv6 address GP_6TO4 ::3334:0:0:0:3/128
```

We can use the general-prefix information to help us configure a null route so that traffic for CSR3 is not sent over the tunnel, as we did on CSR9 and CSR10 earlier. It makes sense to copy/paste the general-prefix when building the static route to avoid making a mistake.

```

R3#show ipv6 general-prefix
IPv6 Prefix GP_6TO4, acquired via 6to4
  2002:A03:403::/48 Valid lifetime infinite, preferred lifetime infinite
    Loopback0 (Address command)
    Loopback0 (Address command)

! CSR3
ipv6 route 2002:A03:403::/48 null0

```

6to4 scales very well because there is nothing special we have to do on the existing 6to4 sites to communicate to CSR3 now. As long as they can reach CSR3's tunnel source (IPv4 address), the sites will communicate. A quick test from CSR3 shows that there is reachability to both CSR9 and CSR10.

```

R3#ping 2002:A09:B09:9999::9 source 2002:A03:403:3333::3
Type escape sequence to abort.
Sending 5, 100-byte ICMP Echos to 2002:A09:B09:9999::9, timeout is 2 seconds:
Packet sent with a source address of 2002:A03:403:3333::3
!!!!
Success rate is 100 percent (5/5), round-trip min/avg/max = 1/7/22 ms

```

```

R3#ping 2002:A0A:D0A:AAAA::A source 2002:A03:403:3334::3
Type escape sequence to abort.
Sending 5, 100-byte ICMP Echos to 2002:A0A:D0A:AAAA::A, timeout is 2 seconds:
Packet sent with a source address of 2002:A03:403:3334::3
!!!!
Success rate is 100 percent (5/5), round-trip min/avg/max = 2/7/22 ms

```

6to4 suffers from some inflexibilities, though. The prefix always begins with 2002::/16, which may not fit nicely into the addressing scheme developed by an organization or service provider. Furthermore, all 32 bits of the IPv4 address must be included in the IPv6 prefix, which can be wasteful if all IPv4 tunnel IPs share some common octets. The subnet ID is always 16 bits as well, so this is a hard upper-bound on the number of usable subnets in an organization. There is also an unpredictability associated with deploying it since the IPv4 relay address of 192.88.99.0/24 is commonly used for Internet access. This is an anycast address which could be anywhere at any time, and poor routing decisions made in the SP network could affect customer traffic negatively. 6RD improves upon these shortfalls as seen next. Neither 6to4 nor 6RD was really designed to support dynamic IGPs, which are supported on manual, GRE, and ISATAP tunnels (semi-dynamic on ISATAP).

36.4.3 6 Rapid Deployment (6RD)

6RD operates very similarly to 6to4 but overcomes the inflexibilities and relay issues inherent to 6to4 designs. The 6RD prefix format is an important concept since it is very flexible and warrants some explanation. The entire IPv6 prefix still must be 64 bits long, but is the concatenation of the IPv6 prefix, IPv4 address, and subnet ID. These are all variable length fields, and as long as the bit-wise sum of their prefix lengths is 64, 6RD can support it. The individual components are explained below:

1. **IPv6 prefix:** This was fixed at 2002::/16 with 6to4. A provider may allocate a different block of addresses for a specific customer, say 200B:CC00::/24. This allows providers to intelligently carve their IPv6 prefixes for customers.
2. **IPv4 address:** 6to4 used all 32 bits of the IPv4 tunnel IP inside the IPv6 address. This makes sense in the case that the IPv4 addresses are totally different. Inside of a private WAN controlled by a provider, these addresses can be prescribed, and possibly assigned sequentially. This often means that the left-most bits in the IP address won't change. For example, if three customer sites have IP addresses 10.20.30.1, 10.20.30.2, and 10.20.30.3, at least the first 24 bits are all identical. There is no reason to waste 24 bits of the IPv6 address to carry this information if 6RD is aware of the similarities. As such, only differing bits (that is, $32 - 24 = 8$) can be carried in the 6RD prefix.
3. **Subnet ID:** When using 6to4, there were 16-bits remaining for the subnet ID. This can be larger if more subnets are needed for a site, but at the cost of having a less specific prefix and/or less IPv4 address bits represented. This is the third contributor to the 64-bit limit for the 6RD prefix and is not configured explicitly since it is a function of the difference: $64 - \text{IPv6 prefix} - \text{IPv4 address} = \text{subnet ID range}$. Evaluating the example above, a 24 bit prefix plus an 8 bit IPv4 address equals 32, which leaves 32 bits available for subnet IDs. That significantly increases the number of subnets available for a given site.

The actual prefixes for the example above are shown below. The IPv6 prefix of 200B:CC00::/24 is combined with the last 8 bits of the IPv4 address (tunnel source) to create a unique prefix per site.

1. Site 1 (10.20.30.1): 200B:CC01::/32
2. Site 2 (10.20.30.2): 200B:CC02::/32
3. Site 3 (10.20.30.3): 200B:CC03::/32

As an adjustment, let's assume the IPv4 addresses are now required to change in the third octet. This means only the first 16 bits of the IPv4 address are consistent between all sites in the 6RD mesh, so we must now include the 8-bit third octet inside the 6RD prefix. This means there are 8 bits less for subnet IDs, which results in 24 bits available for subnet IDs, which is still better than 16 with 6to4. I am keeping the math simple by adjusting at convenient bit-boundaries, but you don't have to.

1. Site 1 (10.20.185.1): 200B:CCB9:0100::/40
2. Site 2 (10.20.30.2): 200B:CC1E:0200::/40
3. Site 3 (10.20.99.3): 200B:CC63:0300::/40

Next, we will configure 6RD on CSR7 and CSR8 to start. We will introduce CSR4 (PE) and XRv2 (Internet) later. CSR7 uses the general-prefix method while CSR8 configures the IPv6 addressing manually. Like 6to4, we can build a general-prefix based on the 6RD prefix which is auto-calculated. Since all PE-CE links begin with 10.x.x.x, we assume only the first octet is common between all sites and specify this as the "ipv4 prefix-len". 6RD is smart enough to subtract this number from 32 and encoded the remaining 24

bits of the IPv4 address inside the final 6RD prefix. We manually specify the IPv6 prefix at whatever length we want; since this is a small 6RD deployment, a /32 has been allocated instead of something typically larger. This means that there are 8 bits left for the subnet ID ($32 + 24 = 56$), which means there can only be 256 subnets per site. Both CSR7 and CSR8 configure some loopback addresses inside their 6RD prefix, much like 6to4. Notice that the subnet IDs are only 8 bits in this setup. Last, we configure a static route which directs traffic for this general /32 prefix out of the tunnel, much like we did for 2002::/16 with 6to4. We also ensure that traffic local to the site (we know this based on the constructed prefix) does not get sent over the tunnel using a null route.

```
! CSR7
ipv6 general-prefix GP_6RD 6rd Tunnel7812

interface Tunnel7812
  description 6RD

  tunnel mode ipv6ip 6rd
  tunnel 6rd ipv4 prefix-len 8
  tunnel 6rd prefix 2003:1E84::/32

interface Loopback0
  ipv6 address 2003:1E84:80D:888::8/128
  ipv6 address 2003:1E84:80D:888::88/128

ipv6 route 2003:1E84:80D:800::/56 Null0
ipv6 route 2003:1E84::/32 Tunnel7812
```

We can verify the tunnels using a custom show command. This shows the important tunnel characteristics including IPv4 source and prefix length (only 10.0.0.0/8 is common), along with the configure IPv6 prefix. The “general prefix” at the bottom shows the post-calculation 6RD prefix for the site. The first 32 bits are fixed as the specified IPv6 prefix, the next 24 bits represents the last 24 bits of

the IPv4 address per site, and the remaining 8 bits are available for the subnet ID. Even though we didn't configure a general-prefix on CSR8, the calculation still gets done, and this show command can be useful for verifying the static null routes.

```
R7#show tunnel 6rd
Interface Tunnel7812:
  Tunnel Source: 10.2.7.7
  6RD: Operational, V6 Prefix: 2003:1E84::/32
    V4 Prefix, Length: 8, Value: 10.0.0.0
    V4 Suffix, Length: 0, Value: 0.0.0.0
  General Prefix: 2003:1E84:207:700::/56
```

```
R8#show tunnel 6rd
Interface Tunnel7812:
  Tunnel Source: 10.8.13.8
  6RD: Operational, V6 Prefix: 2003:1E84::/32
    V4 Prefix, Length: 8, Value: 10.0.0.0
    V4 Suffix, Length: 0, Value: 0.0.0.0
  General Prefix: 2003:1E84:80D:800::/56
```

Like 6to4, we will verify the routing next. The route is static via the 6RD tunnel and the CEF table says an IPv4 lookup must be performed to build the encapsulation for these packets.

```
R8#show ipv6 route 2003:1E84:207:700::/56
Routing entry for 2003:1E84::/32
  Known via "static", distance 1, metric 0
  Route count is 1/1, share count 0
  Routing paths:
    directly connected via Tunnel7812
    Last updated 01:50:13 ago

R8#show ipv6 cef 2003:1E84:207:700:: internal | begin output
output chain:
  IPV6 midchain out of Tunnel7812, addr :: 7F069FA84EC8
  Lookup in table IPv4:Default
```

The encapsulation details are similar to 6to4 with some extra information. The destination IPv4 address is still gleaned from the tunneled IPv6 address, but we can see some extra fields to describe how to handle this process. It copies 24 bits from right to left (start at the 32nd bit and copy 24 of them) which essentially grabs the 24 least significant bits. The IP protocol is still 41, like a manual or 6to4 tunnel.

```
R8#show adjacency tunnel7812 :: encapsulation
Protocol Interface Address
IPV6 Tunnel7812 ::(7)
  Encap length 20
  4500000000000000FF29A4C50A080D08
  00000000
```

```

Provider: TUNNEL
Protocol header count in macstring: 1
HDR 0: ipv4
    dst: static and per packet, copy from payload:
        addr msb 10.0.0.0, addr lsb 0.0.0.0

    prot: static, 41
    ttl: static, 255
    df: static, cleared
    per packet fields: dst tos ident tl chksum

```

Next, we will capture packets on CSR7 outbound and initiates pings on CSR8. This will capture CSR7's echo-replies so we can see the encapsulation. It looks very similar to 6to4; protocol 41 (cyan) with IPv4 source/destination on the outside, and the appropriate IPv6 addressing on the inside. Yellow and green represent source and destination addresses, respectively, as usual.

```

```

Last, we will bring CSR4 into the 6RD network. This is loosely analogous to a LISP PxTR since it will provide interworking between 6RD and non-6RD sites. It is known as a border router (BR, sometimes called border relay) and requires no special configuration. 6RD does work inside of a VRF, so we must configure the tunnel VRF (for endpoint reachability) and the VRF on the tunnel itself (for passing traffic to the Internet). The VRF configuration is not specific to its role as a BR, but I wanted to test the VRF capabilities of 6RD. CSR4 doesn't have any loopbacks since it's just a transit router for the 6RD clients. CSR4 uses the general-prefix for simplicity and configures the static routes as required. The difference is that the static default route points towards XRv2 for Internet access.

```

! CSR4
ipv6 general-prefix GP_6RD 6rd Tunnel17812

interface Tunnel17812
    description 6RD
    vrf forwarding 6RD
    ipv6 address GP_6RD ::4/128
    tunnel source 10.4.12.4
    tunnel mode ipv6ip 6rd
    tunnel vrf 6RD
    tunnel 6rd ipv4 prefix-len 8

```

```
tunnel 6rd prefix 2003:1E84::/32

ipv6 route vrf 6RD 2003:1E84:40C:400::/56 Null0
ipv6 route vrf 6RD 2003:1E84::/32 Tunnel7812
ipv6 route vrf 6RD ::/0 GigabitEthernet2.542 FE80::12
```

The 6RD clients need to identify the BR by IPv4 address and configure static default routes towards the IPv6 address of the BR, which gives them Internet connectivity. The IPv4 address is revealed clearly with the 6RD show command in green. We can glean the IPv6 address of the BR by looking at its 6RD general-prefix and adding the host address to it. We could also check CSR4's IPv6 interface assignments to be sure. These are shown in yellow.

```
R4#show tunnel 6rd
Interface Tunnel7812:
  Tunnel Source: 10.4.12.4
  6RD: Operational, V6 Prefix: 2003:1E84::/32
      V4 Prefix, Length: 8, Value: 10.0.0.0
      V4 Suffix, Length: 0, Value: 0.0.0.0
  General Prefix: 2003:1E84:40C:400::/56
```

```
R4#show ipv6 interface brief tunnel7812
Tunnel7812                [up/up]
  FE80::A04:C04
  2003:1E84:40C:400::4
```

```
! CSR7 and CSR8 (all 6RD clients)
interface Tunnel7812
  tunnel 6rd br 10.4.12.4

ipv6 route ::/0 2003:1E84:40C:400::4
```

For brevity we will only verify CSR8 since CSR7 has an identical configuration. After adding the BR configuration, we can verify it with the 6RD show command. The BR is a fancy way of building a static P2P tunnel from a 6RD client to the BR; specifying the remote IPv4 address is effectively specifying a tunnel destination. This is loosely analogous to a static NHRP mapping on a spoke towards an NHS. We can confirm this by checking the encapsulation details for CSR4's IPv6 address in the 6RD tunnel on CSR8. The destination is static which does not require an IPv4 FIB lookup and the encapsulation string is complete already. All of the other 6to4 and 6RD encapsulation strings needed to fill this in dynamically based on the destination IPv6 packet.

```
R8#show tunnel 6rd
Interface Tunnel7812:
  Tunnel Source: 10.8.13.8
  6RD: Operational, V6 Prefix: 2003:1E84::/32
      V4 Prefix, Length: 8, Value: 10.0.0.0
      V4 Suffix, Length: 0, Value: 0.0.0.0
```

Border Relay address: 10.4.12.4

```

We quickly verify Internet reachability (test loopbacks added to XRv2 are not shown here) from both CSR7 and CSR8. Notice that the prefix starting with 2323 is not part of the 6RD network at all, but the 6RD clients have reachability by following their IPv6 default routes towards the BR.

```
R7#ping 2323::1212 source 2003:1E84:207:777::7
Type escape sequence to abort.
Sending 5, 100-byte ICMP Echos to 2323::1212, timeout is 2 seconds:
Packet sent with a source address of 2003:1E84:207:777::7
!!!!!!
Success rate is 100 percent (5/5), round-trip min/avg/max = 4/8/22 ms
```

```
R8#ping 2323::1212 source 2003:1E84:80d:888:0:0:0:88
Type escape sequence to abort.
Sending 5, 100-byte ICMP Echos to 2323::1212, timeout is 2 seconds:
Packet sent with a source address of 2003:1E84:80D:888::88
!!!!!!
Success rate is 100 percent (5/5), round-trip min/avg/max = 3/7/20 ms
```

Another interesting concept of 6D is specifying a common suffix. This can be configured in lieu of or in addition to the common prefix for IPv4. For example, in our case, every site's IPv4 address begins with 10.x.x.x. If the sites all began with 10.x.x.x and ended with .1, then all of them would fit the format of 10.x.x.1. In this case, we can specify that the first 8 bits and last 8 bits are common, which means 6RD only needs to carry the middle 16 bits. This is an additional size-optimization for when sites have very common configurations; for example, all 6RD tunnel endpoints could have host address .1 and begin with the same first two octets, and the third octet changes per customer. In this case, only the third octet (8 bits) would need to be carried in the 6RD prefix. The concept is identical to the prefix concept

except starts counting from the least-significant bit rather than the most-significant bit, so it is not tested here.

36.4.4 Intra-Site Automatic tunnel Addressing Protocol (ISATAP)

ISATAP tunnels are, by the virtue of their name, designed for connectivity between nodes within a given site. In this example, we use for it WAN tunneling alongside GRE, 6to4, and 6RD tunnels. This is possible but generally not the use-case; ideally, a router would hand out IPv6 prefixes and clients could auto-configure addresses on their ISATAP tunnels to reach one another in a site. The concepts are similar to 6to4 in that the IPv4 address is embedded within the IPv6 address, except this time it is not part of the prefix. An alternative EUI-64 mechanism is used on ISATAP tunnels to develop the IPv6 address and it relies on the tunnel source rather than the Ethernet MAC. CSR1 and CSR5 run ISATAP with one another and glean their IPv6 LL addresses via EUI-64 (by default). There is nothing fancy about the configuration so far.

```
! CSR1
interface Tunnel15
  description ISATAP
  ipv6 enable
  tunnel source 10.1.11.1
  tunnel mode ipv6ip isatap

! CSR5
interface Tunnel15
  description ISATAP
  ipv6 enable
  tunnel source 10.2.5.5
  tunnel mode ipv6ip isatap
```

When we check the IPv6 LL addresses on the tunnel, we can see that only the least significant 32-bits were modified. ISATAP uses the same decimal-to-hexadecimal conversion method as 6to4 by taking the full IPv4 address and embedded it in the IPv6 address without trying to optimize bit-boundaries like 6RD. The 32 bits preceding this IPv4 address are always 0000:5EFE, which is the buffer similar to the FFFE inserted in the middle of the MAC address when using ordinary EUI-64. Again, normally ISATAP clients would derive addresses from an ISATAP router rather than (improperly) use it for inter-site communications as I demonstrate here.

```
R1#show ipv6 interface brief tunnel15
Tunnel15          [up/up]
                  FE80::5EFE:A01:B01

R5#show ipv6 interface brief tunnel15
Tunnel15          [up/up]
                  FE80::5EFE:A02:505
```

Before continuing, we will check LL address reachability over the tunnel. As always, we verify the encapsulation with EPC. CSR1 will capture outgoing packets and CSR5 will initiate pings. We can see the IP protocol remains 41 since this is an IPv6-in-IPv4 tunnel (not GRE). IPv4/IPv6 source addresses are shown in yellow with destinations in green. Notice that the converted IPv4 addresses are included at the very end (least significant bits) of the IPv6 addresses, which is different from 6RD and 6to4.

```
R5#ping FE80::5EFE:A01:B01
Output Interface: tunnel15
Type escape sequence to abort.
Sending 5, 100-byte ICMP Echos to FE80::5EFE:A01:B01, timeout is 2 seconds:
Packet sent with a source address of FE80::5EFE:A02:505%Tunnel15
!!!!
Success rate is 100 percent (5/5), round-trip min/avg/max = 3/8/22 ms
```

```
R1#show monitor capture CAP buffer dump

0050: 015E117D 00000001 02030405 06070809 .^.}.....
```

One interesting benefit of ISATAP is being able to run IGP over it. While there is no mechanism to transport IPv6 multicast traffic (which means no IGP or PIM neighbor discovery), we can use unicast neighbors over the tunnel to exchange routes. Using OSPFv3, for example, we can use network P2MP non-broadcast and specify the remote LL address as the neighbor. Since the tunnels have direct LL reachability, there is nothing stopping OSPFv3 from converging. Obviously, configuring the LL address neighbors of every node in the ISATAP mesh scales poorly, but this is a demonstration of the capability.

```
! CSR1 and CSR5
interface Tunnel15
  ospfv3 15 ipv6 area 0
  ospfv3 15 ipv6 network point-to-multipoint non-broadcast
  ospfv3 15 ipv6 hello-interval 10

! CSR1 only
interface Tunnel15
  ospfv3 15 ipv6 neighbor FE80::5EFE:A02:505

! CSR5 only
interface Tunnel15
  ospfv3 15 ipv6 neighbor FE80::5EFE:A01:B01
```

On CSR5, we verify the OSPFv3 neighbor is up. We only verify one side for brevity.

```
R5#show ospfv3 15 ipv6 neighbor
```

```
OSPFv3 15 address-family ipv6 (router-id 10.5.5.5)
```

Neighbor ID	Pri	State	Dead Time	Interface ID	Interface
10.1.1.1	0	FULL/ -	00:00:32	20	Tunnel15

We also add some loopbacks into OSPFv3 to ensure we can exchange public IPv6 prefixes. This means we will have OSPFv3 intra-area routes on either side via the ISATAP tunnel.

```
! CSR1
interface Loopback0
  ipv6 address 2001:1111:BABE::1/128
  ipv6 address 2001:1111:BEEF::1/128
  ospfv3 15 ipv6 area 0
```

```
! CSR5
interface Loopback0
  ipv6 address 2001:5555:CAFE::5/128
  ipv6 address 2001:5555:DEED::5/128
  ospfv3 15 ipv6 area 0
```

```
R1#show ipv6 route ospf | begin ^O
O   2001:5555:CAFE::5/128 [110/1000]
    via FE80::5EFE:A02:505, Tunnel15
O   2001:5555:DEED::5/128 [110/1000]
    via FE80::5EFE:A02:505, Tunnel15
```

```
R5#show ipv6 route ospf | begin ^O
O   2001:1111:BABE::1/128 [110/1000]
    via FE80::5EFE:A01:B01, Tunnel15
O   2001:1111:BEEF::1/128 [110/1000]
    via FE80::5EFE:A01:B01, Tunnel15
```

It is interesting to note that the ISATAP CEF lookups are fully built already, unlike 6RD and 6to4. This is because there is actually an IPv6 neighbor relationship (via ND) over the tunnel interface so that LL addressing is exchanged. The IPv4 CEF lookup knows that XRv1 is the next hop towards the destination because the IPv6 CEF table indicates CSR5's LL address the next-hop.

```
R1#show ipv6 route 2001:5555:DEED::5/128
Routing entry for 2001:5555:DEED::5/128

```

```
IP adj out of GigabitEthernet2.511, addr 10.1.11.11 7F27796C6370
```

We can verify the encapsulation string for the ISATAP tunnel as well. The final destination of CSR5 is included as CEF is smart enough to see this information from the next-hop address from the RIB. This is somewhat similar to the 6RD BR routes on the 6RD clients; the remote encapsulation was known because the information was computed ahead of time and written to the adjacency table.

```
R1#show adjacency Tunnel15 FE80::5EFE:A02:505 encapsulation
Protocol Interface Address

Success rate is 100 percent (5/5), round-trip min/avg/max = 3/8/22 ms
```

36.5 IPv4/IPv6 Internet Access over MPLS using NAT44

This lab shows how NAT44 and MPLS cooperate in a network to provide IPv4 Internet access to L3VPN customers. IPv6 Internet access is also demonstrated but without the NAT component. There are 3 general NAT44 solutions:

1. **Perform NAT44 on the CE.** Since the number of CEs is very large, this is a highly distributed solution. The SP never deals with any private source addresses from the customer for Internet-destined traffic and never deals with NAT at all. This requires the most NAT configuration overall

and increases complexity for customers. The complexity is further increased since customers need to perform NAT only for Internet-bound traffic, not for inter-site traffic.

2. **Perform NAT44 on the ingress PE.** The number of ingress PEs is less than the number of CEs, but greater than the number of Internet peering points (probably). This solution has medium complexity and medium scalability as the PE is now responsible for learning private LAN source addresses for Internet-bound traffic. The NAT matching could become complex as the ingress PE would need to differentiate between Internet-bound and private-WAN bound traffic to perform NAT intelligently.
3. **Perform NAT44 on the egress PE.** This solution scales the best as the number of Internet peering points is likely less than the number of user-facing PEs in the network. It also simplifies the NAT rules since inter-customer traffic would never cross a NAT device (the UPE would not perform NAT). The drawback is that the Internet peering router would be performing potentially billions of NAT operations with millions of NAT state entries, so the hardware would need to be very powerful.

The network diagram is shown below. CSR6 and XRv1 are PEs supporting IPv4, IPv6 labeled-unicast (6PE), VPNv4, and VPNv6. CSR4 is the IPv4 Internet gateway and XRv2 is the IPv6 Internet gateway. All other routers are customers that require access to both the IPv4 and IPv6 Internet. The basic IGP, MPLS, and BGP configurations are not shown. To focus on NAT and MPLS interaction, all of the sites are only drawing Internet service and are not connected in any kind of inter-site topology. That is to say, each customer router is its own customer site with no lateral VPN route exchanges.

CSR4 has IPv4 and VPNv4 peers to each PE. XRV2 has IPv6 labeled-unicast and VPNv6 peers to each PE. The purpose of the IPv4/v6 unicast AFs is to support route leaking. This allows the PEs to import the Internet routes from global to VRF (the Internet gateways exported them from VRF to global) as another mechanism for providing central services. Although more complex and sloppier, it assumes that the routers already have Internet routes in their global tables in the first place, so replicating that information in a VPN could be inefficient with respect to memory consumption. We quickly verify these BGP sessions are functional before continuing.

```

Neighbor	Spk	AS	MsgRcvd	MsgSent	TblVer	InQ	OutQ	Up/Down	St/PfxRcd
30.0.0.6	0	30	8925	8420	7	0	0	21:30:05	0
30.0.0.11	0	30	8406	8415	7	0	0	21:29:47	0

The Internet routers are injecting prefixes into AS 30. Both CSR4 and XRv2 store these in a VRF table, which is a central services design. The VRF configuration is shown below for CSR4 and XRv2. The Internet routes are verified to be present inside VPNv4 BGP but with bogus RTs (no one is importing RT:4:999). Within the L3VPN, only the default route needs to be advertised to the remote PEs as this will guarantee the customers do not get the “full view” of all Internet routes. The PEs and other ISP routers, however, may require this full view so that they could be Internet transit points. These are arbitrary requirements fabricated for the purpose of this lab. The export map for VPN attributes on CSR4 appends RT:4:5 to the default route only, which all customer VRFs will import. The export map for route-leaking permits the default route as well as the Internet routing table. CSR4 imports the RTs of all customers to provide central services. The customer VRFs have not been configured yet but we can stage the RT import policies to save time later.

```
! CSR4
ip prefix-list PL_DEFAULT seq 5 permit 0.0.0.0/0

route-map RM_EXPORT_VRF_5 permit 10
 match ip address prefix-list PL_DEFAULT
 set extcommunity rt 4:5 additive

ip prefix-list PL_INTERNET seq 5 permit 55.0.0.0/8 le 32
ip prefix-list PL_INTERNET seq 10 permit 0.0.0.0/0

route-map RM_VRF_5_TO_GLOBAL permit 10
 match ip address prefix-list PL_INTERNET

vrf definition 5
 rd 4:5
 address-family ipv4
  export map RM_EXPORT_VRF_5
  export ipv4 unicast map RM_VRF_5_TO_GLOBAL
  route-target export 4:999
  route-target import 6:2
  route-target import 6:1
  route-target import 6:8
  route-target import 11:8
  route-target import 11:9
  route-target import 11:10
```

The logic is similar on XRv2. XR route leaking logic is simpler than XE since no bogus export-RTs are required. The export policy for RT assigns RT:12:7 to the default route as the parameterized RPL makes clear. The export route leaking policy leaks the default route only. This example might be valuable to provide IPv6 Internet service to a customer not in a VPN, so leaking it at the ingress PE might be easier than leaking it at the egress PE.

```
! XRv2
vrf 7
  address-family ipv6 unicast
    import route-target
      6:1
      6:2
      6:8
      11:8
      11:9
      11:10

    export route-policy RPL_IF_DEST_SET_RT(PS_DEFAULT, RT_12_7)
    export to default-vrf route-policy RPL_IF_DEST_PASS(PS_DEFAULT)

  extcommunity-set rt RT_12_7
    12:7
  end-set

  prefix-set PS_DEFAULT
    ::/0
  end-set

  route-policy RPL_IF_DEST_PASS($PS)
    if destination in $PS then
      pass
    endif
  end-policy

  route-policy RPL_IF_DEST_SET_RT($PS, $RT)
    if destination in $PS then
      set extcommunity rt $RT additive
    endif
  end-policy
```

Now, the Internet VRF is configured to apply the correct behavior to the default route. This will allow it to leak into the global table as well as receive a valid RT so that customers may import it. CSR4 and XRv2 inject static default routes into their Internet VPNs as shown below. This can be advertised towards the central services customers in lieu of the Internet routing table. The minor difference between CSR4 and XRv2 in static route next-hops has a significant impact on MPLS forwarding. This is analyzed later.

```
! CSR4
```

```

ip route vrf 5 0.0.0.0 0.0.0.0 Null0

router bgp 30
  address-family ipv4 vrf 5
    redistribute static
    default-information originate

! XRv2
route-policy RPL_PASS
  pass
end-policy

route-policy RPL_IF_TAG_PASS($TAG)
  if tag is $TAG then
    pass
  endif
end-policy

router static
  vrf 7
  address-family ipv6 unicast
    ::/0 GigabitEthernet0/0/0/0.572 fe80::7 tag 7

router bgp 30
  vrf 7
  rd 12:7
  default-information originate
  address-family ipv6 unicast
    redistribute static route-policy RPL_IF_TAG_PASS(7)

```

Most of the basic configuration is complete on CSR4 and XRv2 at this point. To verify this configuration on CSR4, we can check the default route and any other arbitrary Internet route. The Internet route only has RT:4:999, and the only reason it needs any RT is because route leaking requires it (this is detailed in the route leaking section). The default route carrying the bogus RT in addition to the real one has no significance. This verifies that the RT export-map worked. To verify the route-leaking, we check the global IPv4 BGP RIB. We see both the Internet and default routes, as expected.

```

R4#show bgp vpnv4 unicast vrf 5 55.46.253.0/26 | include RT:
  Extended Community: RT:4:999

```

```

R4#show bgp vpnv4 unicast vrf 5 0.0.0.0/0 | include RT:
  Extended Community: RT:4:5 RT:4:999

```

```

R4#show bgp ipv4 unicast 0.0.0.0/0 | include import
  Local, imported path from 4:5:0.0.0.0/0 (5)

```

```

R4#show bgp ipv4 unicast 55.46.253.128 | include import
  5, imported path from 4:5:55.46.253.128/26 (5)

```

To verify the configuration on XRv2, we follow a similar procedure. The default route gets RT:12:7 which is what all central services customers must import in order to get Internet connectivity. The original IPv6 Internet route has no RTs applied, which is expected. Unlike IPv4, the IPv6 Internet routes are not allowed to leak into the global table; only the default route is. Again, this is just for variety and is not necessary a good design choice. We confirm this by checking the IPv6 RIB. Notice that the default route has a next-hop to be resolved inside VRF 7, as expected.

```
RP/0/0/CPU0:XRv2#show bgp vpnv6 unicast vrf 7 ::/0 | include RT:
    Extended community: RT:12:7
```

```
RP/0/0/CPU0:XRv2#show bgp vpnv6 unicast vrf 7 ::77:babe:3/128 | include RT:

        No advertising protos.
```

```
RP/0/0/CPU0:XRv2#show route ipv6 ::77:babe:3/128
% Network not in table
```

Before continuing, we must understand the forwarding differences between the IPv4 and IPv6 egress PEs given their default route configurations. CSR4 has a VPNv4 route for 0.0.0.0/0 which is a local aggregate. When packets arrive with label 4009, CSR4 removes all labels from the stack, and is directed by the LFIB to consult the IPv4 FIB inside VRF 5. CSR4 would need a longer-match route for the final destination as a result, which it learns via BGP for all Internet routes. This two-step lookup process can be inefficient since the incoming VPN label cannot map to an LFIB next-hop as the underlying RIB does not specify one for the aggregate default route.

```
R4#show bgp vpnv4 unicast vrf 5 0.0.0.0/0
BGP routing table entry for 4:5:0.0.0.0/0, version 169
Paths: (1 available, best #1, table 5)

```
R4#show ip route vrf 5 55.0.0.0 255.0.0.0 longer-prefixes | begin Gate
Gateway of last resort is 0.0.0.0 to network 0.0.0.0
```

```
55.0.0.0/26 is subnetted, 4 subnets
B       55.46.253.0 [20/0] via 10.4.5.5, 22:24:44
B       55.46.253.64 [20/0] via 10.4.5.5, 22:24:44
B       55.46.253.128 [20/0] via 10.4.5.5, 22:24:44
B       55.46.253.192 [20/0] via 10.4.5.5, 22:24:44
```

On XRv2, this problem does not exist. The static route is specified as being accessible via CSR7, so the LFIB can use this when binding the VPN label to the next-hop inside the VRF. This is efficient since only a single lookup needs to occur. In general, this is a better design. Alternative designs could include simply learning a default from the Internet in the first place, if possible.

```

Next, we confirm that the remote PEs (CSR6 and XRv1) learn the IPv4/v6 Internet and default routes. Beginning with the global table on CSR6, we see the full Internet routing table. CSR6 could technically leak the entire IPv4 Internet routing table to a customer, if necessary. For IPv6, only the default route is learned since XRv2 did not leak the IPv6 Internet routing table.

```
R6#show ip route bgp | begin Gate
Gateway of last resort is 30.0.0.4 to network 0.0.0.0
```

```
B*    0.0.0.0/0 [200/0] via 30.0.0.4, 1d13h
      55.0.0.0/26 is subnetted, 4 subnets
B      55.46.253.0 [200/0] via 10.4.5.5, 1d13h
B      55.46.253.64 [200/0] via 10.4.5.5, 1d13h
B      55.46.253.128 [200/0] via 10.4.5.5, 1d13h
B      55.46.253.192 [200/0] via 10.4.5.5, 1d13h
```

```
R6#show ipv6 route bgp | begin Appl
      a - Application
B    ::/0 [200/0]
      via 30.0.0.12%default, indirectly connected
```

Of note, the IPv6 default route also has an associated BGP label from XRv2. This is the result of using 6PE, which is required to tunnel IPv6 traffic across an IPv4-only MPLS core inside the global table.

```
R6#show ipv6 route ::/0
Routing entry for ::/0
  Known via "bgp 30", distance 200, metric 0, type internal
  Route count is 1/1, share count 0
  Routing paths:
    30.0.0.12%default indirectly connected
    MPLS label: 92009
    Last updated 3d11h ago
```

Now that the IPv4/v6 Internet routing advertisements have been verified, we will configure the customer VPNs. CSR6 and XRv1 won't learn any VPNv4/v6 routes until some VRFs are configured to import the RTs the Internet peering routers are exporting (RT retention is always disabled by default). Each CE router will perform a different combination of IPv4 and IPv6 Internet access for variety. CSR9 will use BGP for IPv4 to learn the default route from XRv1 inside of the VPN; this is a traditional central services model. At the same time, the IPv6 default route will be leaked from global to VRF on XRv1. First, we must configure XRv1, the PE, to provide these routing services. For IPv4, the central services RT:4:5 is imported and a unique RT:11:9 is exported. Earlier, we saw RT:11:9 imported by CSR4, which is required for bidirectional connectivity. Under IPv6, no RTs are imported since only global routes are leaked. XRv2 imports RT:11:9 which is exported by XRv1.

```
! XRv1
prefix-set PS_DEFAULT
  ::/0
end-set

route-policy RPL_IF_DEST_PASS($PS)
  if destination in $PS then
```

```

        pass
    endif
end-policy

vrf 9
    address-family ipv4 unicast
        import route-target
        4:5
    export route-target
    11:9

address-family ipv6 unicast
    import from default-vrf route-policy RPL_IF_DEST_PASS(PS_DEFAULT)
    export route-target
    11:9

```

XRv1's corresponding BGP configuration is very straightforward. Since routing information is exchanged with CSR9 in both AFIs, both IPv4 and IPv6 unicast are configured.

```

! XRv1
route-policy RPL_PASS
    pass
end-policy

router bgp 30
    vrf 9
        rd 11:9
        address-family ipv4 unicast
        address-family ipv6 unicast

    neighbor 10.9.11.9
        remote-as 9
        address-family ipv4 unicast
            route-policy RPL_PASS in
            route-policy RPL_PASS out

    neighbor fd00:10:9:11::9
        remote-as 9
        address-family ipv6 unicast
            route-policy RPL_PASS in
            route-policy RPL_PASS out

```

Despite using different methods to import the default route into the IPv4 and IPv6 AFIs within the VPN, the routes generally look the same once imported. Both of them have next-hops in the default table.

```

RP/0/0/CPU0:XRv1#show route vrf 9 ipv4 0.0.0.0/0
Routing entry for 0.0.0.0/0

```

```

```

```
R9#show ipv6 cef ::/0
::/0
  nexthop FE80::11 GigabitEthernet2.591
```

CSR9 has only IPv4 private addressing on its LAN simulated by loopback0. One NAT solution for this “IPv4 Internet access” architecture is to perform NAT on the CE. This is the simplest solution but adds complexity for the customer. This problem does not exist for IPv6, so we configure a public IPv6 subnet on the loopback. The NAT configuration is very basic as CSR9 has a pool of 16 usable IP addresses. A static null route matches the pool and is advertised into BGP so that return traffic routes back to CSR9 properly.

```
! CSR9
interface GigabitEthernet2.591
 ip nat outside

interface Loopback0
 ip address 192.168.9.1 255.255.255.255
 ip nat inside
 ipv6 address 9000::9/16

ip nat pool NAT_POOL 9.0.0.0 9.0.0.15 prefix-length 28
ip nat inside source list ACL_NAT pool NAT_POOL
ip access-list standard ACL_NAT
 permit 192.168.9.0 0.0.0.255

ip route 9.0.0.0 255.255.255.240 Null0

router bgp 9
 address-family ipv4
  network 9.0.0.0 mask 255.255.255.240

 address-family ipv6
  network 9000::/16
```

We verify that the PE learns the IPv4 NAT pool and IPv6 public routes from CSR9. These will ultimately be advertised towards the IPv4/v6 Internet.

```
RP/0/0/CPU0:XRv1#show bgp vrf 9 ipv4 unicast neighbors 10.9.11.9 routes |
begin Network
```

Network	Next Hop	Metric	LocPrf	Weight	Path
Route Distinguisher: 11:9 (default for vrf 9)					
*> 9.0.0.0/28	10.9.11.9	0		0	9 i

```
RP/0/0/CPU0:XRv1#show bgp vrf 9 ipv6 unicast neighbors fd00:10:9:11::9 routes
| begin Network
```

Network	Next Hop	Metric	LocPrf	Weight	Path
Route Distinguisher: 11:9 (default for vrf 9)					

```
*> 9000::/16          fd00:10:9:11::9          0          0 9 i
```

We quickly confirm that the Internet routers CSR5 and CSR7 learn these routes originated by CSR9. This completes the control plane verification.

```
R5#show bgp ipv4 unicast 9.0.0.0/28

Total number of translations: 2
```

XRv1 imposes two MPLS labels to transport the IPv4 packets towards CSR4. The VPN label was allocated by CSR4 to describe the path towards the default route; since XRv1 has no longer-matching VPN route

for 55.46.253.1, the label 4009 for the default route is used. Label 3001 is CSR3's LDP label for 34.0.0.4/32.

30.0.0.3:0     3001
```

CSR3 performs PHP as a P router to expose label 4009 to CSR4. When CSR4 receives label 4009, the LFIB directs the router to perform another lookup inside the VRF 5 FIB. This is because 0.0.0.0/0 was a local aggregate and CSR4 cannot forward the packet based on the MPLS label alone.

```
R3#show mpls forwarding-table labels 3001

```

When CSR5 responds, it sends its replies to 9.0.0.0. CSR4 imposes two labels just as XRv1 did in the opposite direction. Label 91003 is the VPN label for 9.0.0.0/28 from XRv1 and label 3002 is CSR3's LDP binding for 30.0.0.11/32.

```
R4#show ip cef vrf 5 9.0.0.0

```

CSR3 is a P router performing PHP and XRv11 forwards packets towards CSR9. Since 9.0.0.0/28 was not a local aggregate defined on XRv1, we do not see the inefficiency of multiple LFIB/FIB lookups on XRv1 as we did on CSR4. When CSR9 receives the packets on the outside interface, NAT happens before routing, so the destination of 9.0.0.0 is changed back to 192.168.9.1 and the packet is routed to the loopback.

```
R3#show mpls forwarding-table labels 3002

CSR9's connectivity to the IPv6 Internet is less interesting as there is no NAT in play. Rather than trace the LSPs for a very basic L3VPN connection (the route leaking as already verified), I use traceroute from CSR9 (CE) and CSR7 (IPv6 Internet) for brevity. 2 labels are imposed by the ingress LSR in either direction as expected, and the packets are label-switched across the core. The only interesting part of the output below is label 92009; this is technically an IPv6 labeled-unicast label, not a VPNv6 label, since the route

was imported from the global table. When XRv2 leaked the route from VRF to global, a new local label was allocated and advertised via BGP IPv6 labeled-unicast.

```
R9#traceroute ipv6
Target IPv6 address: ::77:BABE:0

A quick verification on XRv2 proves that a new label was issued; the VPNv6 label of 92008 was not carried over during the VRF-to-global export process. This is the label learned by XRv1 in the global table.

```
RP/0/0/CPU0:XRv2#show bgp vpnv6 unicast vrf 7 ::/0 | include Local Label
Local Label: 92008
```

```
RP/0/0/CPU0:XRv2#show route ipv6 ::/0 detail | include Local Label
Local Label: 0x16769 (92009)
```

```
RP/0/0/CPU0:XRv1#show route ipv6 unicast ::/0 detail | include Label
Label: 0x16769 (92009)
```

Next, we will use a set of alternative techniques on CSR2 and CSR8. Like CSR9, these are CE routers with private IPv4 addressing, and thus require NAT. CSR6, the ingress PE, will perform NAT for these clients. This means that CSR6 will need to learn the private addresses from the CE and not distribute them indiscriminately to the IPv4 Internet. For IPv6, both clients will be in a basic L3VPN central services VPN. This is usually the best approach for IPv6 Internet connectivity when only a default route is required. For brevity, CSR2 and CSR8 interface configurations are not shown, but their private networks are

192.168.2.1/24 and 192.168.8.1/24, respectively. The IPv6 networks 2000::/16 and 8000::/16 are used by CSR2 and CSR8, respectively, as well. First, I show the VPN-specific configurations on CSR6. There is no route leaking with this example; the VRFs just perform standard RT import/export actions. The only imported RT for both VRFs is the central services RT for each AFI.

```
! CSR6
vrf definition 2
  rd 6:2
  address-family ipv4
    route-target export 6:2
    route-target import 4:5

  address-family ipv6
    route-target export 6:2
    route-target import 12:7

vrf definition 8
  rd 6:8
  address-family ipv4
    route-target export 6:8
    route-target import 4:5

  address-family ipv6
    route-target export 6:8
    route-target import 12:7
```

Next, we configure BGP on the PE. CSR6 has the responsibility to ensure that private routes learned from the customer are not advertised further. Rather than actually match the private range, CSR6 marks all routes from the customers with the “no-advertise” community, which prevents it from being advertised at all. This solution works well when the customer is ONLY sending private routes to the CE and there is no possibility of public IPv4 routes being advertised.

```
! CSR6
route-map RM_SET_NO_ADV permit 10
  set community no-advertise

router bgp 30
  address-family ipv4 vrf 2
    neighbor 10.2.6.2 remote-as 2
    neighbor 10.2.6.2 activate
    neighbor 10.2.6.2 route-map RM_SET_NO_ADV in

  address-family ipv6 vrf 2
    neighbor FD00:10:2:6::2 remote-as 2
    neighbor FD00:10:2:6::2 activate

  address-family ipv4 vrf 8
```

```
neighbor 10.6.8.8 remote-as 8
neighbor 10.6.8.8 activate
neighbor 10.6.8.8 route-map RM_SET_NO_ADV in
```

```
address-family ipv6 vrf 8
neighbor FD00:10:6:8::8 remote-as 8
neighbor FD00:10:6:8::8 activate
```

Below are the basic BGP configurations on CSR2 and CSR8. They advertise their private networks to CSR6 and do not perform local NAT44.

```
! CSR2
router bgp 2
no bgp default ipv4-unicast
neighbor 10.2.6.6 remote-as 30
neighbor FD00:10:2:6::6 remote-as 30
```

```
address-family ipv4
network 192.168.2.0
neighbor 10.2.6.6 activate
```

```
address-family ipv6
network 2000::/16
neighbor FD00:10:2:6::6 activate
```

```
! CSR8
router bgp 8
no bgp default ipv4-unicast
neighbor 10.6.8.6 remote-as 30
neighbor FD00:10:6:8::6 remote-as 30
```

```
address-family ipv4
network 192.168.8.0
neighbor 10.6.8.6 activate
```

```
address-family ipv6
network 8000::/16
neighbor FD00:10:6:8::6 activate
```

Before configuring NAT on CSR6, we verify that the PE learns the private IPv4 routes from both customers and the “no-advertise” community is set. The IPv6 routes are also present but lack this community as they are public and can be advertised to the IPv6 Internet.

```

```

NAT configuration, even when crossing VRFs, is very simple. Inside interfaces are configured towards the customer (inside VRF) and outside interfaces are configured towards the MPLS core (global interfaces). Two NAT pools are defined, along with corresponding VRF-aware static null routes. NAT rules are applied within a VRF to perform NAT source translation for the private networks within AS 2 and AS 8. There is nothing different about the NAT configuration other than ensuring the static routes and NAT rules are VRF-aware.

```

! CSR6
interface GigabitEthernet2.536
 ip nat outside

interface GigabitEthernet2.526
 ip nat inside

interface GigabitEthernet2.568
 ip nat inside

ip nat pool NAT_POOL_2 2.0.0.0 2.0.0.15 prefix-length 28
ip nat pool NAT_POOL_8 8.0.0.0 8.0.0.15 prefix-length 28

ip route vrf 2 2.0.0.0 255.255.255.240 Null0
ip route vrf 8 8.0.0.0 255.255.255.240 Null0

ip access-list standard ACL_NAT_2
 permit 192.168.2.0 0.0.0.255
ip access-list standard ACL_NAT_8
 permit 192.168.8.0 0.0.0.255

ip nat inside source list ACL_NAT_2 pool NAT_POOL_2 vrf 2
ip nat inside source list ACL_NAT_8 pool NAT_POOL_8 vrf 8

```

To complete the configuration, the static null routes defined above are advertised into BGP via network statements. To ensure these routes are not advertised down to the customers, a prefix-list that only permits the default route is applied. Although learning these NAT pool routes are harmless for CSR2 and CSR8, it is sloppy from a design perspective.

```

! CSR6
ip prefix-list PL_DEFAULT seq 5 permit 0.0.0.0/0

router bgp 30
 address-family ipv4 vrf 2
  network 2.0.0.0 mask 255.255.255.240
  neighbor 10.2.6.2 prefix-list PL_DEFAULT out

 address-family ipv4 vrf 8
  network 8.0.0.0 mask 255.255.255.240
  neighbor 10.6.8.8 prefix-list PL_DEFAULT out

```

As a quick verification, we confirm that CSR5 (IPv4 Internet) learns the routes to 2.0.0.0/28 and 8.0.0.0/28, but do not see routes for any private networks. We also confirm that CSR2 and CSR8 (CE routers) do not learn the NAT pools that CSR6 defined; they only learn the default routes for IPv4 as seen earlier.

```
R5#show bgp ipv4 unicast 2.0.0.0/28

To test connectivity, CSR2 and CSR8 both attempt to ping the IPv4 Internet from their loopbacks. The pings succeeds (not shown) and CSR6 creates NAT state for each. Since overloading is not used, outside-to-inside traffic is also permitted when using an ACL with NAT pool; this is just an observation and is not relevant for this test. The post-NAT IPv4 source addresses for CSR2 and CSR8 are 2.0.0.0 and 8.0.0.0, respectively.

R6#show ip nat translations

Pro	Inside global	Inside local	Outside local	Outside global
---	2.0.0.0	192.168.2.1	---	---
---	8.0.0.0	192.168.8.1	---	---
icmp	2.0.0.0:6	192.168.2.1:6	55.46.253.193:6	55.46.253.193:6
icmp	8.0.0.0:5	192.168.8.1:5	55.46.253.193:5	55.46.253.193:5

Because this IPv4 Internet access is provided via a central services architecture, the MPLS label stack is identical for VRFs 2 and 8 as the exact same VPN route is used. Rather than trace this basic LSP, we will end the forward-LSP verification here.

R6#show ip cef vrf 2 55.46.253.193

0.0.0.0/0

nexthop 30.3.6.3 GigabitEthernet2.536 label 3001 4009

R6#show ip cef vrf 8 55.46.253.193

0.0.0.0/0

nexthop 30.3.6.3 GigabitEthernet2.536 label 3001 4009

Returning traffic is very similar except there are 2 separate VPN routes on CSR4 which originated in different VRFs (one per NAT pool). The transport label is the same but the VPN label differs in this case. Nonetheless, this is basic L3VPN and does not warrant additional verification.

R4#show ip cef vrf 5 2.0.0.0/28

2.0.0.0/28

nexthop 30.3.4.3 GigabitEthernet2.534 label 3000 6013

R4#show ip cef vrf 5 8.0.0.0/28

8.0.0.0/28

nexthop 30.3.4.3 GigabitEthernet2.534 label 3000 6020

What is interesting is how a command like “ip nat outside” can be honored when traffic entering CSR6 from CSR3 is MPLS encapsulated. The reason this configuration works is because CSR6 locally generated the static null routes for 2.0.0.0/28 and 8.0.0.0/28. This means that the label action on CSR6 will be to

strip all labels and perform an IPv4 VRF-aware FIB lookup on the destination. As seen above, labels 6013 and 6020 were allocated by CSR6 for the NAT pools.

```
R6#show mpls forwarding-table labels 6013
```

Local Label	Outgoing Label	Prefix or Tunnel Id	Bytes Label Switched	Outgoing interface	Next Hop
6013	No Label	2.0.0.0/28 [V]	1770	aggregate/2	

```
R6#show mpls forwarding-table labels 6020
```

Local Label	Outgoing Label	Prefix or Tunnel Id	Bytes Label Switched	Outgoing interface	Next Hop
6020	No Label	8.0.0.0/28 [V]	1180	aggregate/8	

However, performing a VRF-aware routing lookup on 2.0.0.0/28 or 8.0.0.0/28 will drop traffic as these are connected to null0. Because outside NAT happens before routing, the traffic is un-NAT'ed first and then the routing lookup occurs. The key is that the order of operations still applies with respect to MPLS label removal, outside NAT, and routing. After the label is removed, the order of operations "restarts" for IP traffic. After un-NAT, traffic is forwarded back towards the proper customer.

```
R6#show ip cef vrf 2 2.0.0.0/28
```

```
2.0.0.0/28
```

```
attached to Null0
```

```
R6#show ip cef vrf 8 8.0.0.0/28
```

```
8.0.0.0/28
```

```
attached to Null0
```

IPv6 Internet connectivity in this design is uninteresting as it is a basic L3VPN central services design with no complexity. A quick traceroute within the customer VRFs confirms this works properly.

```
R2#traceroute ipv6
```

```
Target IPv6 address: ::77:BABE:2
```

```
Source address: 2000::2
```

```

We will examine another set of Internet connectivity methods on CSR1. For IPv4, CSR6 will leak the default IPv4 route from global into the VRF. CSR1 has no requirement for NAT44 as it only supports a few users, so using direct public addressing is acceptable. We will assume that CSR1 is an older router that cannot support IPv6 BGP, so instead uses a static default route. The prefix-list filter is applied as a best practice to ensure CSR1 does not become overloaded with IPv4 Internet routes accidentally. No RTs are imported into VRF 1 for IPv4, so this accidental advertisement is currently impossible. Since CSR6 cannot learn CSR1's public IPv6 routes, we configure a VRF-aware static route and redistribute it into BGP.

```

! CSR6
route-map RM_VRF_1_IMPORT_BGP permit 10
  match ip address prefix-list PL_DEFAULT

vrf definition 1
  rd 6:1
  address-family ipv4
    import ipv4 unicast map RM_VRF_1_IMPORT_BGP
    route-target export 6:1

  address-family ipv6
    route-target export 6:1
    route-target import 12:7

ipv6 route vrf 1 1000::/16 GigabitEthernet2.516 FE80::1 tag 1

route-map RM_STATIC_TO_BGP_VRF_1 permit 10
  match tag 1

router bgp 30
  address-family ipv4 vrf 1
    neighbor 10.1.6.1 remote-as 1
    neighbor 10.1.6.1 activate
    neighbor 10.1.6.1 prefix-list PL_DEFAULT out

  address-family ipv6 vrf 1
    redistribute static route-map RM_STATIC_TO_BGP_VRF_1

```

The most interesting part of this configuration is the global-to-VRF route leaking. CSR6 learns the route inside the default table natively. Once it is exported from global (imported to VRF), the route is marked "af-export" with the VRF name of the target VRF. The newly-created VPN route has no RTs or MPLS

labels, but does specify a global next-hop. The reason labels are not required is because the MPLS core is IPv4-capable, so if the penultimate hop removes the transport label and exposes the IPv4 header to the egress PE, the egress PE can route it correctly.

```
R6#show bgp ipv4 unicast 0.0.0.0
BGP routing table entry for 0.0.0.0/0, version 25

    30.0.0.4 (metric 20) (via default) from 30.0.0.4 (30.0.0.4)
      Origin incomplete, metric 0, localpref 100, valid, internal, no-import,
no-import, best
      rx pathid: 0, tx pathid: 0x0
```

The configuration on CSR1 is very basic. The loopback prefix of 1.0.0.0/28 is advertised into BGP so CSR6 can learn it. A default IPv6 route is also configured which complements the specific 1000::/16 static route added onto CSR6.

```
! CSR1
router bgp 1
  no bgp default ipv4-unicast
  neighbor 10.1.6.6 remote-as 30

address-family ipv4
  network 1.0.0.0 mask 255.255.255.240
  neighbor 10.1.6.6 activate

ipv6 route ::/0 GigabitEthernet2.516 FE80::6
```

We quickly confirm that CSR6 learns 1.0.0.0/28 from CSR1 and CSR1 learns the default route from CSR6.

```
R6#show bgp vpnv4 unicast vrf 1 1.0.0.0/28

```

Because no VPN label was allocated for the default route when it was leaked into the VRF, only one label is imposed. This is the LDP label from CSR3 to describe the path to 30.0.0.4/32.

```

R6#show ip cef vrf 1 55.46.253.1 detail
0.0.0.0/0, epoch 0, flags [rib only nolabel, rib defined all labels, default
route]
recursive via 30.0.0.4
  nexthop 30.3.6.3 GigabitEthernet2.536 label 3001

```

```

lib entry: 30.0.0.4/32, rev 9
  remote binding: lsr: 30.0.0.3:0, label: 3001

```

When CSR3 pops this label, the IPv4 packet is exposed to CSR4. Since CSR4 leaked the Internet route from VRF to global, it has a route for the final destination in the global table. The next-hop is in VRF 5, but connectivity still works. Only a single MPLS label is required to tunnel the traffic through the P routers as there is no need to bind VPN labels for IPv4 prefixes in the global table. The exception was 6PE, which is required when the core is not IPv6-capable (verified on CSR9 earlier).

```

```

Traffic in the reverse direction uses basic L3VPN for transport. Since CSR6 learns 1.0.0.0/28 via BGP, label 6011 actually forwards traffic directly to CSR1 inside the VPN. This is different than the static null routes for 2.0.0.0/8 and 8.0.0.0/28 observed earlier for NAT support.

```

R4#show ip cef vrf 5 1.0.0.0/28

```

For IPv6, the default route was imported into VRF 1 using the normal RT-import process. This is why label 92008, the original VPNv6 label allocated by XRv2, is used. This is in contrast to XRv1 where label 92009 was used (IPv6 labeled-unicast) since route leaking was used at the IPv6 Internet peering point. Returning traffic in the reverse direction is also using a basic L3VPN forwarding scheme.

```

CSR8 can be multi-homed to XRv1 as well. Normally this would call for providing the full routing table to CSR8, but an alternative approach is to use simply BGP manipulations to prefer one default gateway over the other. We will examine IPv6 first, saving the final NT44 option for later. XRv1 will simply provide a default route, just like CSR6. By importing RT:12:7, this will match the default route and nothing else. We confirm that only the IPv6 default route is imported before continuing.

```
! XRv1
vrf 8
 address-family ipv6 unicast
   import route-target
     12:7
   export route-target
     11:8

router bgp 30
vrf 8
 rd 11:8
 address-family ipv6 unicast

 neighbor fd00:10:8:11::8
   remote-as 8
   address-family ipv6 unicast
     route-policy RPL_PASS in
     route-policy RPL_PASS out
```

```
RP/0/0/CPU0:XRv1#show bgp vpnv6 unicast vrf 8 | begin Network
      Network      Next Hop      Metric LocPrf Weight Path
Route Distinguisher: 11:8 (default for vrf 8)
*>i::/0            30.0.0.12            0      100      0 ?
```

Next, we configure CSR8 for BGP IPv6 unicast. The configuration is very basic, and to ensure XRv1 is used, we adjust the weight for that peer. Otherwise, CSR8 will prefer the older default route when comparing CSR6 and XRv1. The other BGP parameters, such as the network statements, are already configured on CSR8 from earlier. I add a lower weight to CSR6 just for clarity, although it is not required. This will make configuration adjustments easier later. We confirm that CSR8 learns both IPv6 default routes and prefers XRv1 over CSR6 due to the BGP weight attribute.

```
! CSR8
router bgp 8
 neighbor FD00:10:8:11::11 remote-as 30
 address-family ipv6
  neighbor FD00:10:6:8::6 weight 66
  neighbor FD00:10:8:11::11 activate
  neighbor FD00:10:8:11::11 weight 1111

```

We confirm that XRv1 learns CSR8's public IPv6 prefix 8000::/16. Because the exported RT is something that XRv2 is already importing, we assume that this route is being advertised to the IPv6 Internet. Again, this is basic L3VPN so traceroute is used to speed up the verification.

```
RP/0/0/CPU0:XRv1#show bgp vrf 8 ipv6 unicast 8000::/16 | begin " 8$"
 8

```

We progress to CSR10's IPv6 connectivity. Similar to CSR9, XRv1 will leak the default IPv6 route from the global table. The difference is that CSR10 is an old router, like CSR1, and is incapable of running BGP IPv6. It uses a static default route to reach the IPv6 Internet. XRv1 configures a VRF-aware static route to CSR1's public IPv6 prefix A000::/16. Some RPL infrastructure is re-used to selectively redistribute this into BGP.

```
! XRv1
prefix-set PS_10
  a000::/16
end-set

vrf 10
  address-family ipv6 unicast
    import from default-vrf route-policy RPL_IF_DEST_PASS(PS_DEFAULT)
    export route-target
      11:10

router bgp 30
  vrf 10
    rd 11:10
    address-family ipv6 unicast
      redistribute static route-policy RPL_IF_DEST_PASS(PS_10)

! CSR10
ipv6 route ::/0 GigabitEthernet2.510 FE80::1
```

Because the prefix A000::/16 was locally originated into BGP but was not a null aggregate (that is, it has a valid next-hop), a prefix-specific VPNv6 label is allocated. The export RT of 11:10 is imported by XRv2 so it is assumed this prefix can be reached from the IPv6 Internet.

```
RP/0/0/CPU0:XRv1#show bgp vpnv6 unicast vrf 10 a000::/16

```

As a quick review, the IPv6 labeled-unicast label of 92009 is used since the core is not IPv6-aware. This was allocated by XRv2 since traffic received from the core will use this label and the LFIB lookup occurs in the global table. When XRv2 receives traffic along this LSP, label stack is removed and traffic is forwarded to CSR7.

```

RP/0/0/CPU0:XRv1#show cef vrf 10 ipv6 ::/0

```

Using traceroute, we can verify IPv6 Internet connectivity. Label 92009 is technically an IPv6 labeled-unicast label from XRv2, but on XRv1, it is used as a VPNv6 label at imposition. The label carries over when the prefix is imported from default to VRF. IPv6 Internet connectivity is significantly more straightforward, even with route leaking, than IPv4 as there is seldom a need for NAT.

```

R10#traceroute ipv6
Target IPv6 address: ::77:BABE:3
Source address: A000::A
[snip]
Tracing the route to ::77:BABE:3
 1 ::FFFF:30.3.11.11 4 msec 3 msec 2 msec
 2 ::FFFF:30.3.11.3 [MPLS: Labels 3003/92009 Exp 0] 8 msec 8 msec 8 msec
 3 FD00:10:7:12::12 [MPLS: Label 92009 Exp 0] 23 msec 22 msec 22 msec
 4 FD00:10:7:12::7 23 msec 15 msec 15 msec

```

This completes IPv6 Internet connectivity for all CE routers. CSR8's link via XRv1 and CSR10 have not yet been enabled for IPv4 Internet connectivity. There is a third option that this document has not yet

explored. The first option was local NAT on the CE device as seen on CSR9. The second option was NAT on the ingress PE as seen on CSR6 supporting CSR2 and CSR8. The third option is NAT on the egress PE towards the IPv4 Internet. This might be used when there are many ingress PEs and a small set of very powerful IPv4 Internet peering routers. The NAT44 can be centralized on these routers rather than managed on the ingress PEs. The drawback is that increase in processing power as a result of the consolidating NAT44 processing on a smaller set of devices. First, the VRF RT import/export policies are defined. There is no route-leaking with this solution to keep the focus on NAT44.

```
! XRv1
vrf 8
  address-family ipv4 unicast
    import route-target
      4:5
    export route-target
      11:8

vrf 10
  address-family ipv4 unicast
    import route-target
      4:5
    export route-target
      11:10
```

Next, BGP is configured between the CEs (CSR10 and CSR8) and XRv1. Weight is used on CSR8 to prefer XRv1 for testing, just as it was in IPv6. The BGP configuration is very simple as there is no route leaking or advanced filtering. The most interesting part of this configuration is that CSR8 and CSR10 advertise their private LAN routes to XRv1, and XRv1 makes no effort to filter them. This is because the routes must be advertised all the way to XRv2, the NAT44 point.

```
! CSR8
router bgp 8
  neighbor 10.8.11.11 remote-as 30
  address-family ipv4
    network 192.168.8.0
    neighbor 10.6.8.6 weight 66
    neighbor 10.8.11.11 activate
    neighbor 10.8.11.11 weight 1111

! CSR10
router bgp 10
  no bgp default ipv4-unicast
  neighbor 10.10.11.11 remote-as 30
  address-family ipv4
    network 192.168.10.0
    neighbor 10.10.11.11 activate

! XRv1
```

```

router bgp 30
vrf 8
address-family ipv4 unicast
neighbor 10.8.11.8
remote-as 8
address-family ipv4 unicast
route-policy RPL_PASS in
route-policy RPL_PASS out

```

```

router bgp 30
vrf 10
address-family ipv4 unicast
neighbor 10.10.11.10
remote-as 10
address-family ipv4 unicast
route-policy RPL_PASS in
route-policy RPL_PASS out

```

Before continuing, we quickly verify that XRv1 learns the routes from both CEs. We also verify that both CEs learn a default from XRv1. CSR8 learns the same route from CSR6 and XRv1, but prefers XRv1 due to the BGP weight configuration.

```

RP/0/0/CPU0:XRv1#show bgp vpnv4 unicast 192.168.8.0/22 longer-prefixes |

To protect the IPv4 Internet from learning these private LAN routes, a basic prefix filter is applied outbound on CSR4. This denies all private and IPv4 link-local prefixes, as well as the default route. The default route prefix-list is reused from before and contained in the route-map match clause using Boolean “or” logic. A quick check on CSR5 ensures that these private routes are not learned.

```

! CSR4
ip prefix-list PL_PRIVATE seq 5 permit 10.0.0.0/8 le 32
ip prefix-list PL_PRIVATE seq 10 permit 172.16.0.0/12 le 32
ip prefix-list PL_PRIVATE seq 15 permit 192.168.0.0/16 le 32
ip prefix-list PL_PRIVATE seq 20 permit 169.254.0.0/16 le 32

route-map RM_INTERNET_OUT deny 10
  match ip address prefix-list PL_DEFAULT PL_PRIVATE
route-map RM_INTERNET_OUT permit 100

router bgp 30
  address-family ipv4 vrf 5
    neighbor 10.4.5.5 route-map RM_INTERNET_OUT out

```

```

R5#show bgp ipv4 unicast 192.168.8.0/22 longer-prefixes
[no output]

```

Next, we configure NAT44 on CSR4. Unlike the other NAT44 configurations, we use port overloading on CSR4. This is not specific to running NAT on the egress PE; I introduce it here for variety only. The NAT pools contain a single route and there are corresponding VRF-aware static routes per pool. Although the NAT interfaces are in different VRFs, the router seamlessly moves packets across as necessary. CSR4 creates ACLs to match the private LANs on both CSR8 and CSR10 which are used for the inside NAT rules. These rules are also VRF-aware.

```

! CSR4
interface GigabitEthernet2.534
  ip nat inside

interface GigabitEthernet2.545
  ip nat outside

ip nat pool NAT_POOL_8 4.8.0.0 4.8.0.0 prefix-length 30
ip nat pool NAT_POOL_10 4.10.0.0 4.10.0.0 prefix-length 30

```

```

ip route vrf 5 4.8.0.0 255.255.255.255 Null0
ip route vrf 5 4.10.0.0 255.255.255.255 Null0

ip access-list standard ACL_NAT_10
 permit 192.168.10.0 0.0.0.255
ip access-list standard ACL_NAT_8
 permit 192.168.8.0 0.0.0.255

ip nat inside source list ACL_NAT_10 pool NAT_POOL_10 vrf 5 overload
ip nat inside source list ACL_NAT_8 pool NAT_POOL_8 vrf 5 overload

```

The BGP configuration involves redistributing these static routes. Since there is a VRF-aware default route already being redistributed into BGP, we technically don't need to configure anything new. The configuration is shown again for reference, but this command was already configured to advertise the VRF-aware default into BGP. We quickly confirm that these NAT pool prefixes were advertised into BGP properly.

```

! CSR4, reference only
address-family ipv4 vrf 5
 redistribute static

```

```

R4#show bgp vpnv4 unicast vrf 5 4.8.0.0/14 longer-prefixes | begin Network
      Network          Next Hop          Metric LocPrf Weight Path
Route Distinguisher: 4:5 (default for vrf 5)
Export Map: RM_VRF_5_TO_GLOBAL, Address-Family: IPv4 Unicast, Pfx
Count/Limit: 5/1000
*> 4.8.0.0/32          0.0.0.0          0          32768 ?
*> 4.10.0.0/32         0.0.0.0          0          32768 ?

```

Because CSR4's export RT policy for VRF 5 adds a bogus RT by default, these NAT pool routes carry that RT. No router imports this RT anywhere in the network and it was only required to force route leaking to work. As such, no fancy filtering is required to prevent the CEs from learning these NAT pool routes. XRv1 is unable to import either route as shown below.

```

R4#show bgp vpnv4 unicast vrf 5 4.8.0.0/32 | include RT:
      Extended Community: RT:4:999

```

```

R4#show bgp vpnv4 unicast vrf 5 4.10.0.0/32 | include RT:
      Extended Community: RT:4:999

```

```

RP/0/0/CPU0:XRv1#show bgp vpnv4 unicast vrf 8 4.8.0.0/32
% Network not in table

```

```

RP/0/0/CPU0:XRv1#show bgp vpnv4 unicast vrf 10 4.10.0.0/32
% Network not in table

```

Of greater importance is ensuring the IPv4 Internet (CSR5) learns these routes. We quickly confirm that below. This completes the control-plane verification as all of the routing information is correct.

```
R5#show bgp ipv4 unicast 4.8.0.0/14 longer-prefixes | begin Network
      Network      Next Hop      Metric LocPrf Weight Path
*>  4.8.0.0/32      10.4.5.4          0           0 30 ?
*>  4.10.0.0/32     10.4.5.4          0           0 30 ?
```

When traffic arrives at XRv1 from the customers, it follows the exact same LSP since both paths recursive to the default route. The transport LSP using label 3001 has been traced multiple times already, so that part is skipped.

```
RP/0/0/CPU0:XRv1#show cef vrf 8 55.46.253.193 | include labels
      next hop 30.3.11.3/32 Gi0/0/0/0.531 labels imposed {3001 4009}
```

```
RP/0/0/CPU0:XRv1#show cef vrf 10 55.46.253.193 | include labels
      next hop 30.3.11.3/32 Gi0/0/0/0.531 labels imposed {3001 4009}
```

When CSR4 receives label 4009, it is directed to perform an ordinary IPv4 FIB lookup in VRF 5. Because the IPv4 packet is revealed to CSR4, it can perform inside NAT on this traffic. The MPLS label identified the proper VRF which will specify which NAT rule to use.

```
R4#show mpls forwarding-table labels 4009
Local      Outgoing   Prefix      Bytes Label  Outgoing   Next Hop
Label      Label      or Tunnel Id Switched     interface
4009       No Label   0.0.0.0/0[V] 6490         aggregate/5
```

```
R4#show ip cef vrf 5 55.46.253.193
55.46.253.192/26
      nexthop 10.4.5.5 GigabitEthernet2.545
```

Because NAT overload is used, there are no outside-to-inside mappings created. The post-NAT source addresses are 4.8.0.0 and 4.10.0.0, which are the only IPv4 addresses available in each pool. Since CSR4 learns the original private addresses (inside locals), those are identified so that the return flow can be un-NAT'ed.

```
R4#show ip nat translations
Pro Inside global   Inside local   Outside local   Outside global
icmp 4.8.0.0:1      192.168.8.1:6  55.46.253.193:6 55.46.253.193:1
icmp 4.10.0.0:1     192.168.10.1:5 55.46.253.193:5 55.46.253.193:1
Total number of translations: 2
```

Because outside NAT happens before routing, the reply traffic destination to 4.8.0.0 or 4.10.0.0 is translated back into the correct inside local address as identified in the NAT translation table. Since the

return path is regular L3VPN, two labels are imposed, and the VPN label differs for each as these are unique, non-aggregate prefixes. This completes the return path.

```
R4#show ip cef vrf 5 192.168.8.0
192.168.8.0/24
  nexthop 30.3.4.3 GigabitEthernet2.534 label 3002 91009

R4#show ip cef vrf 5 192.168.10.0
192.168.10.0/24
  nexthop 30.3.4.3 GigabitEthernet2.534 label 3002 91004
```

Additional Reading – Reference configurations "inet-access"

37. Describe, implement, and troubleshoot end-to-end fast convergence

37.1 Loop Free Alternate (LFA) for IPv4

IPv4 LFA is supported for OSPFv2, IS-IS, and EIGRP. The purpose of this feature is to create a loop-free path from a given node by running SPF using other routers as the root of the tree (not including EIGRP, which is discussed in a dedicated section). Specifically, a router with LFA configuration only runs SPF from the perspective of its neighbors, not every router in the area/level, as the local router is just trying to find a backup next-hop towards a specific destination. Because all of the LFA testing was all done using the same topology, the configurations are provided once. To move through the demonstrations, all you need to do is shutdown or enable certain interfaces, change administrative distances, enable/disable LFA where desired, tune metrics, etc. All of the IGP's for both IPv4 and IPv6 have been pre-built.

Additional Reading (includes all direct and IPv4 rLFA examples) – Reference configurations "lfa"

37.1.1 OSPFv2

37.1.1.1 Direct LFA

The network diagram is shown below. Many diverse IGP paths are used so that testing the different LFA variables is made easy.

The basic LFA configuration is shown below, beginning with the XE routers. LFA is enabled on a per-prefix basis, which is the only option supported on XE (XR also supports per-link, which is discussed later). The concept of prefix-priority is related to the order in which prefixes are updated in the RIB/FIB after SPF is finished. Higher priorities are processed first, and generally these are loopbacks (LSP endpoints) or IPTV SSM sources. A route-map can be applied to select prefixes for high-priority, but the default is /32 prefixes. Prefix-priority is not discussed in detail as it is very straightforward.

```
! All XE routers
router ospf 1
  fast-reroute per-prefix enable area 0 prefix-priority high
```

A quick summary on CSR1 shows the default tiebreaker policy for backup paths. The tiebreakers are used to select the best backup when multiple backups exist. These are examined in great detail.

```
CSR1#show ip ospf fast-reroute
      OSPF Router with ID (1.1.1.1) (Process ID 1)
Loop-free Fast Reroute protected prefixes:
      Area      Topology name  Priority  Remote LFA Enabled
      0          Base         High      No
Repair path selection policy tiebreaks (built-in default policy):
 10  srlg
 20  primary-path
 30  interface-disjoint
 40  lowest-metric
 50  linecard-disjoint
 60  node-protecting
```

```
70 broadcast-interface-disjoint
256 load-sharing
```

To simplify the output initially, I have increased the cost of CSR1's LAN segment and P2P CSR4 link to 5. This gives us a single best-path through P2P CSR2 connection, which is a good starting point. I have configured all of the CSRs to keep all backup paths, even ignored ones, as this will make troubleshooting easier. The command consumes more memory with little operational gain other than more information seen to the administrator. It is very useful for troubleshooting as we will see soon.

```
! CSR1
interface GigabitEthernet2.513
 ip ospf cost 5

interface GigabitEthernet2.514
 ip ospf cost 5

! All XE routers
router ospf 1
 fast-reroute keep-all-paths
```

Let's examine how CSR1 sees XRv14's loopback with IPv4 address 14.14.14.14/32. For readability, I am breaking the output of this command into sections and describing each section individually.

```
CSR1#show ip ospf rib 14.14.14.14 255.255.255.255
      OSPF Router with ID (1.1.1.1) (Process ID 1)
      Base Topology (MTID 0)
OSPF local RIB
Codes: * - Best, > - Installed in global RIB
LSA: type/LSID/originator
```

The first entry is the best path via the P2P link. The “RIB” flag without the “Repair” flag is an indication that this is the best path.

```
*> 14.14.14.14/32, Intra, cost 3, area 0
    SPF Instance 20, age 00:00:19
    Flags: RIB, HiPrio
    via 12.0.0.2, GigabitEthernet2.512
    Flags: RIB
    LSA: 1/14.14.14.14/14.14.14.14
```

This is the repair path via XRv13 over the LAN. When compared against the best path, it is a different interface (and by extension a different broadcast interface), is downstream to the destination (closer), and provides node protection since CSR2 is not in the repair path. These are all “good” things that generally make a repair path more desirable. Having repair paths rely on the same interfaces, same linecards, and same nodes may result in lower availability.

```
repair path via 123.0.0.13, GigabitEthernet2.513, cost 7
Flags: RIB, Repair, IntfDj, BcastDj, CostWon, NodeProt, Downstr
LSA: 1/14.14.14.14/14.14.14.14
```

This candidate path was ignored because of the cost tiebreaker. The path is also interface disjoint but has a higher cost than the path shown above.

```
repair path via 14.0.0.4, GigabitEthernet2.514, cost 8
Flags: Ignore, Repair, IntfDj, BcastDj, NodeProt
LSA: 1/14.14.14.14/14.14.14.14
```

This path is equal in many ways to the selected repair path, but was ignored due to not providing node protection. This is another link through CSR2, so LFA would rather use a different node in the transit path, all other more important things being equal. Node protection guarantees that if CSR2 fails completely, the LFA does not rely on CSR2 as the next-hop.

```
repair path via 123.0.0.2, GigabitEthernet2.513, cost 7
Flags: Ignore, Repair, IntfDj, BcastDj, Downstr
LSA: 1/14.14.14.14/14.14.14.14
```

Let's say we want to use CSR4 as the backup path. We can use the shared risk link group (SRLG) to identify the PSP CSR2 and LAN interfaces as sharing risk; that is, we don't want to re-route traffic between two links in the same SRLG because perhaps they use the same fiber pair or physical conduit. This is an administrative setting similar to the MPLS-TE SRLG and serves an identical purpose, except that it is local only (not carried in topology information).

```
! CSR1
interface GigabitEthernet2.512
  srlg gid 222

interface GigabitEthernet2.513
  srlg gid 222
```

The paths sharing the SRLG are marked in the OSPF RIB with the "SRLG" flag and are now ignored. Notice that CSR4 is technically not "downstream" from CSR1 towards the destination. This is because both nodes have a cost of 3 to reach 14.14.14.14/32, and like the EIGRP feasibility condition, the next-hop node must be strictly closer (lower metric, cannot be equal) to the destination. CSR4 is also higher cost than those LAN interfaces, but SRLG is the first and most important tiebreaker by default. This is the "trump card" that can administratively exclude certain links from LFA consideration. CSR4 is the highest cost backup path, but is also the most desirable.

```
CSR1#show ip ospf rib 14.14.14.14 255.255.255.255
[snip]
*> 14.14.14.14/32, Intra, cost 3, area 0
    SPF Instance 21, age 00:07:24
```

```

Flags: RIB, HiPrio
  via 12.0.0.2, GigabitEthernet2.512
    Flags: RIB
    LSA: 1/14.14.14.14/14.14.14.14
  repair path via 14.0.0.4, GigabitEthernet2.514, cost 8
    Flags: RIB, Repair, IntfDj, BcastDj, NodeProt
    LSA: 1/14.14.14.14/14.14.14.14
  repair path via 123.0.0.13, GigabitEthernet2.513, cost 7
    Flags: Ignore, Repair, IntfDj, BcastDj, SRLG, NodeProt, Downstr
    LSA: 1/14.14.14.14/14.14.14.14
  repair path via 123.0.0.2, GigabitEthernet2.513, cost 7
    Flags: Ignore, Repair, IntfDj, BcastDj, SRLG, Downstr
    LSA: 1/14.14.14.14/14.14.14.14

```

With the SRLGs in place, next we will change some OSPF costs. The cost on the CSR2 P2P link (on CSR1 side) has been set to 5 with other CSR1 link costs set to 1. The cost on CSR2 to XRv14 has been increased to 2, making CSR1 select the LAN interface via XRv13 to reach 14.14.14.14/32. I did not remove the SRLG, so the best-path is through an interface with SRLG set. This means that we don't really want to use the CSR2 P2P link as a backup. It also has a worse cost, so even without the SRLG, CSR2 P2P link would not be preferred.

```

! CSR1
interface GigabitEthernet2.512
  ip ospf cost 5

```

```

interface GigabitEthernet2.513

CSR1#show ip ospf rib 14.14.14.14 255.255.255.255
[snip]
*> 14.14.14.14/32, Intra, cost 3, area 0
  SPF Instance 25, age 00:00:11
  Flags: RIB, HiPrio
    via 123.0.0.13, GigabitEthernet2.513
      Flags: RIB
      LSA: 1/14.14.14.14/14.14.14.14
    repair path via 14.0.0.4, GigabitEthernet2.514, cost 4
      Flags: RIB, Repair, IntfDj, BcastDj
      LSA: 1/14.14.14.14/14.14.14.14
    repair path via 12.0.0.2, GigabitEthernet2.512, cost 8
      Flags: Ignore, Repair, IntfDj, SRLG

```

```
LSA: 1/14.14.14.14/14.14.14.14
```

The prove the claim above, we remove the SRLGs; the end result in the same, but cost is the differentiator. Notice that the path through CSR4 is not considered node-protecting because CSR4 has equal cost paths through XRv13 and CSR5 to reach 14.14.14.14/32. That is, we cannot guarantee that if we fast-reroute traffic to CSR4 that CSR4 won't forward it through XRv13. CSR4's ECMP load-sharing mechanism could potentially forward traffic through XRv13 which means node-protection cannot be assumed. Node-protection was not analyzed for this LFA decision, but confirming the observation is good practice.

```
! CSR1

      Route metric is 3, traffic share count is 1
      Repair Path: 45.0.0.5, via GigabitEthernet2.545
```

We will attempt to make CSR1's LFA shown above "node-protecting". A quick cost adjustment on CSR4 (increase cost on link towards XRv13 to 2) shows the path above as being node-protected since CSR4 is only routing through CSR5. This doesn't change the LFA selection but is just an interesting note. Personally, even if node-protection is low on the tiebreaker list, I would try to design the network such

that node-protection was made available as often as possible. Now XRv13 could fail completely and it would have no affect on the backup path, which was not the case before the CSR4 cost adjustment.

```
! CSR4
interface GigabitEthernet2.534

  LSA: 1/14.14.14.14/14.14.14.14
```

One final example shows the best-path through XRv13 with the CSR4 P2P link disabled. CSR1 can select either link on CSR2, which is both downstream and node-protecting. LFA should select the P2P link versus the LAN interface as it interface-disjoint (disjoint meaning the same LAN interface was not re-used). To facilitate this, CSR2's cost on the LAN interface is increased to 2 because if CSR2 routes to XRv13 over that link, it is not loop free, and cannot be a backup path. The below output shows that the path through the CSR2 P2P link was selected based on "IntfDj". The path is also broadcast interface disjoint but that was not considered (this particular option is discussed later). Of note, notice that the cost through this preferred backup path is higher than the ignored one; this is because interface disjoint is processed before lowest metric by default.

```

    LSA: 1/14.14.14.14/14.14.14.14
```

To modify the tiebreaker options, you can manually configure a new sequence. In this example, we re-apply an SRLG to CSR1 CSR P2P and LAN interfaces. We then tell OSPF that SRLG disjoint is required (not just preferred), as are downstream nodes. Notice that changing the selection process wipes out the default settings, so you cannot make a few changes and maintain the default policy. You'd need to redefine the entire selection process. CSR1 only cares about the SRLG-disjoint and downstream characteristics now; cost, for example, is not considered by LFA at all.

```
! CSR1
interface GigabitEthernet2.512
  srlg gid 45

interface GigabitEthernet2.513
  srlg gid 45

! CSR1
router ospf 1
  fast-reroute per-prefix tie-break srlg required index 10
  fast-reroute per-prefix tie-break downstream required index 20

CSR1#show ip ospf fast-reroute
[snip]
Repair path selection policy tiebreaks:
  10  srlg (required)
  20  downstream (required)
  256 load-sharing
```

All OSPF costs have been reset to 1 on CSR2. The link between CSR1 and CSR4 has been enabled again. CSR1's cost on the LAN interface has been set to 5, making the P2P CSR2 link the best path. However, notice how there is no backup path. The path through CSR2 and XRv13 on the LAN is not available because it shares an SRLG with the primary path (but one is downstream). The link through CSR4 is not

available because it is not downstream to the destination (both have a cost of 3), but passes the SRLG test. This demonstrates the danger of using the "required" keyword for LFA tiebreakers as the logic between required options is Boolean AND, not Boolean OR. All conditions must be true, but in our case we have 3 candidate repair paths that are ignored because no single path meets both criteria.

```
! CSR2
interface GigabitEthernet2.513
 ip ospf cost 1

! CSR1
interface GigabitEthernet2.514
 no shutdown

interface GigabitEthernet2.513

   LSA: 1/14.14.14.14/14.14.14.14
```

A quick fix would be to somehow make CSR4 downstream (closer) to 14.14.14.14/32. If we increase the cost on CSR1's P2P interface to CSR2 to a number less than 5, CSR1 could potentially pick CSR4 as a best-path. Let's assume we want to keep the current best-path (via the CSR2 P2P link) but use CSR4 as a repair-path without modifying the tie-breakers. Increasing the cost on both the CSR2 and XRv13 P2P links to XRv14, followed by increasing the cost on CSR1's P2P link to CSR4, should meet the goal. The first modification would make CSR1 think that CSR2, XRv13, and CSR4 are all equidistant from XRv14. Increasing the cost on CSR1's P2P link to CSR4 ensures that the best-path is maintained and CSR4 is now considered downstream.

```
! CSR2
```

```

interface GigabitEthernet2.524
  ip ospf cost 2

! Xrv13
router ospf 1
  area 0
    interface GigabitEthernet0/0/0/0.534
      cost 2

! CSR1
interface GigabitEthernet2.514
  ip ospf cost 2

```

Now, the path through CSR4 is both downstream (CSR4's cost is 3, CSR1's cost is 4, and $3 < 4$) and does not share an SRLG with the primary path. It is a valid backup-path per our tie-breaker configuration. Before continuing, those custom tie-breaker commands are removed.

```

    LSA: 1/14.14.14.14/14.14.14.14

```

An interesting corner-case is using the broadcast-interface-disjoint tiebreaker. This ensures that an LFA does not transit through the same broadcast interface used by the primary path, but from the perspective another router. For example, if CSR1 selects the best path via Xrv13 (LAN interface) to reach 14.14.14.14/32, if CSR2 was an LFA, it is preferable for CSR2 not to follow the path CSR2 > Xrv13 > Xrv14. This would cause the primary and backup paths to both rely on the same LAN, which is what the BcastDj option attempts to avoid. Instead, the LFA via CSR4 > Xrv13 > Xrv14 is a better option. Adjusting costs as shown below ensures that Xrv13 > Xrv14 is the primary path, but the LFA via CSR2 is ignored because it uses the same LAN as the primary path.

```

```

Next, we will do some basic tests with XR direct LFA using OSPFv2. The network has been reset with all OSPF costs set to 1 and all interfaces enabled (cleanup not shown). We enable per-prefix LFA under area 0 which applies to all area 0 interfaces also (by inheritance). This is applied on XRv14 only since XRv13 will be used for per-link LFA later.

```

! XRv14
router ospf 1
 area 0
  fast-reroute per-prefix

```

Examining the route to CSR1's loopback, we see two equal cost paths, both of which back each other up. Notice they are primary paths (both are used for ECMP), downstream (both CSR2 and XRv13 are closer

to CSR1 than XRv14 is), node protecting (the paths do not rely on the same transit routers), and SRLG disjoint.

```

      Attributes: Metric: 3, Primary, Downstream, Node Protect, SRLG
Disjoint
```

We can see another path through CSR5 by looking at the diagram but OSPF does not display it here. We will apply SRLGs to XRv14's interfaces facing CSR2 and XRv13 so that we prefer not to use backup paths that way. We make SRLG the #1 tiebreaker also, following the same convention tested with XE earlier. Additionally, we will increase the cost of XRv14's interface facing CSR2 to 2 so that ECMP is not in play. Notice that applying SRLGs in XR is identical across LFA and MPLS-TE. In XE, there are two different mechanisms, but XR consolidates this nicely.

```

```

Let's make CSR5 downstream somehow. We accomplish this by significantly increasing all of XRv14's metrics so that all neighbors appear downstream. We will also increase CSR2's metric by even more so that it loses the LFA tie-break based on worse cost. To prove that metric is the tie-breaker, we will put the downstream attribute as the #2 item in the tie-breaker process.

```

! XRv14
router ospf 1
  fast-reroute per-prefix tiebreaker downstream index 2
  area 0

```

We now reset all the costs on XRv14 back to 1 (not shown) and shift focus to XRv13. We will briefly test per-link LFA, which is an alternative LFA technique. Per-link runs SPF for all prefixes learned through a primary next-hop. This is obviously less ideal as certain links will not yield LFA paths for all prefixes, but is significantly less CPU intensive. This is only supported on XR and appears to be a less popular variant of LFA. I use a medium prefix-priority just for variety, although it doesn't mean much in a network where we are only evaluating loopback addresses.

```

! XRv13
router ospf 1
  fast-reroute per-link priority-limit medium
  area 0
  fast-reroute per-link

```

Based on the output below, we can conclude the following. The “(!)” symbol indicates an FRR path.

Prefixes with next-hop 123.0.0.1 (1.1.1.1/32, 4.4.4.4/32) use CSR4 34.0.0.4

Prefixes with next-hop 123.0.0.2 (2.2.2.2/32) use XRv14 43.0.0.14

Prefixes with next-hop 43.0.0.14 (5.5.5.5/32, 14.14.14.14/32) use CSR 123.0.0.2

Prefixes with next-hop 34.0.0.4 (5.5.5.5/32, 4.4.4.4/32) use CSR1 123.0.0.1

```

RP/0/0/CPU0:XRv13#show route ospf

```

If we add several prefixes to (or behind) XRv14, their FRR paths will be identical to 14.14.14.14/32 regardless of the number of prefixes we add and without additional computation. I've added 4 to demonstrate the point. Of course, the result would be the same with per-prefix, but with additional computation for each prefix. When the network has an enormous number of prefixes, it is likely that the number of links on a router is significantly less than the number of prefixes, so this can be a way of scaling LFA.

```
RP/0/0/CPU0:XRv13#show route longer-prefixes 14.14.14.0/24 | begin ^O

```

37.1.1.2 Remote LFA

In ring designs with 4 or more nodes, you cannot use regular LFA to reach some nodes (assuming all costs are equal) since your neighbors sometimes route through you. The network has been modified by setting all OSPF costs to 1, shutting down the shared LAN interface, removing SRLGs, and removing CSR5 completely. CSR1's tiebreaker policies have been set to the default values. We now have a pentagon shape where all costs are equal (CSR1-CSR2-XRv14-XRv13-CSR4-CSR1). If CSR1 tries to compute a backup-path to CSR2's loopback, CSR4 says that it routes through CSR1 to get there. This is not going to work for ordinary LFA as it is not a loop-free path. Remote LFA (rLFA) logic solves this problem by applying the following logic: "I can tunnel the traffic to a node that CAN reach CSR2 through a backup path (like XRv13) and let that node deliver the traffic". In this scenario, each node will have a backup path for nodes that are exactly two hops away; for example, CSR1 has backup paths for XRv13 and XRv14, but not CSR2 and CSR4. This is using regular LFA with no modifications, but ideally we want to protect paths to CSR2 and CSR4 also around the ring topology. **Note: Only MPLS encapsulation with LDP signaling is currently supported.** LDP is enabled on all OSPF-enabled links in the network (not shown). I suppose this is a limitation of Segment Routing (SR) in that remote-LFA cannot use it for tunnel label bindings.

```
CSR1#show ip ospf rib

    repair path via 14.0.0.4, GigabitEthernet2.514, cost 4

```

Remote LFA introduces several new terms which are discussed first. There are two "spaces" that have been defined to show how remote-LFA works. I derive these definitions from "draft-shand-remote-lfa-00" as they are succinct and clear.

P-space: Set of routers reachable without any path (including ECMP options) transiting the protected link. For example, from CSR1's perspective we are trying to protect a path to CSR2. Our shortest path is the direct link, which is what we are trying to protect, so the P-space routers would not be reachable over that link. A quick look at CSR1's routing table can tell us which routers we CAN reach through the link towards CSR4. Clearly, we can reach CSR4 and XRV13 this way. XRV14 and CSR2 are not considered P-space routers because CSR1's shortest path to them is via the protected link. Attached is a picture to help visualize the P-space; the red colored link is the link we are trying to protect.

```

CSR1#show ip route | include 14.0.0.4
[snip]
O      4.4.4.4 [110/2] via 14.0.0.4, 00:06:40, GigabitEthernet2.514
O      13.13.13.13 [110/3] via 14.0.0.4, 00:09:23, GigabitEthernet2.514

```

Q-space: Set of routers from which the destination can be reached without any path (including ECMP options) transiting the protected link. For example, we are trying to reach CSR2; that is the destination.

Q-space determines which routers can reach CSR2 on their best-paths without transiting the protected link (CSR1-CSR2). We would need to check each router's route to 2.2.2.2/32 to see which ones fit within the Q-space and which don't. I will use traceroute to speed things up. The highlights represent the protected link, which implies the router is NOT part of the Q-space if its path traverses that link. This output reveals that XRv13 and XRv14 are in the Q-space, but CSR1 and CSR4 are not. XRv13 and XRv14 can both reach CSR2 by not transiting the link we are trying to protect. Attached is a picture to help visualize the Q-space.

```

PQ-node: A router that exists in both the P and Q spaces concurrently. The logic is as follows: the source router (CSR1) can reach any P-space router without transiting the protected link. Any Q-space router can reach the destination (CSR2) without transiting the protected link. Therefore, CSR1 can reach XRV13 and XRV13 can reach CSR2 without transiting the protected link. CSR1 establishes a "repair tunnel" to XRV13 (the PQ-node) inside of MPLS. XRV13 is the tail end of this repair tunnel, sending tunneled packets along their natural best-path to CSR2. Attached is a picture to help visualize the PQ-node.

Like regular LFA, the configuration is very straightforward and is demonstrated on CSR1. The first command tells it what kind of encapsulation to use, and right now “mpls-ldp” is the only option. Future encapsulations could potentially include MPLS with Segment Routing, GRE/IP, or any other tunneling techniques. The second command puts an upper-bound on how far the tunnel can go. Realistically, you do not want to tunnel backup traffic too long in your network. In our case, I set an aggressive value of 3 to ensure we do not tunnel traffic more than 2 hops (plus the cost of the loopback). After all, if CSR1 can tunnel traffic to XRV13 (the PQ router), that is all we need in a small 5-node ring. Likewise, in the opposite direction, if we can tunnel to XRV14 as a PQ-node, we can backup CSR4's loopback. I am only enabling rLFA in area 0 although you can omit the area and enable it for all areas (plus external routes). In fact, **you must omit the area if you want to protect external routes**, which implicitly means rLFA is enabled for all areas as well.

```
! CSR1
router ospf 1
  fast-reroute per-prefix remote-lfa area 0 tunnel mpls-ldp
  fast-reroute per-prefix remote-lfa area 0 maximum-cost 3
```

The head-end (CSR1) sends targeted LDP hellos towards 13.13.13.13/32 (and also XRV14 to protect CSR4). We need to enable the PQ-nodes to accept these targeted hellos; we will enable it on XRV13 only first. Notice what happens if you skip this step as we did on XRV14. The LDP neighbor does not form and rLFA will not work. CSR1 picked XRV13 because it was a PQ-router; the algorithm that determined this happens behind the scenes automatically based on the aforementioned P-space / Q-space discussion. You do not need to specify the rLFA tunnel destination, which greatly simplifies the configuration.

```

! XRv13
mpls ldp
  address-family ipv4
    discovery targeted-hello accept

CSR1#show mpls ldp discovery

```

CSR1 learns XRv13's LDP local-label for 2.2.2.2/32 via the rLFA tunnel, which is 93008. This will be the inner label when rLFA traffic is tunneled to XRv13. Also take note of CSR4's label for 2.2.2.2/32, which is 4002, as this will be used after CSR1's SPF process completes and traffic stops forwarding over the rLFA tunnel. Just like TE-FRR in ordinary MPLS, the backup path is only used for a very short time until the tunnel head-end repairs failure. In this case, once IGP is aware of the failure, it uses the backup path immediately (LFA or rLFA) and computes SPF in the meantime. Assuming SPF completes quickly, traffic will follow a new, more stable LSP, which in this case would use label 4002 via CSR4 directly.

```

CSR1#show mpls ldp bindings 2.2.2.2 32
lib entry: 2.2.2.2/32, rev 4
  local binding:  label: 1000
  remote binding: lsr: 4.4.4.4:0, label: 4002
  remote binding: lsr: 2.2.2.2:0, label: imp-null
  remote binding: lsr: 13.13.13.13:0, label: 93008

```

When sending traffic destined to XRv13 (which is the tail end of the rLFA tunnel), we must use CSR4's label for 13.13.13.13/32, which is 4004. This is the outer label for the rLFA tunnel, as well as the targeted LDP session with XRv13.

```

CSR1#show mpls ldp bindings 13.13.13.13 32
lib entry: 13.13.13.13/32, rev 10
  local binding:  label: 1002
  remote binding: lsr: 4.4.4.4:0, label: 4004

```

```
remote binding: lsr: 2.2.2.2:0, label: 2003
remote binding: lsr: 13.13.13.13:0, label: imp-null
```

As seen below, a repair tunnel called "MPLS-Remote-Lfa1" was created to backup this destination. Assuming XRv14 was correctly configured to accept tLDP sessions (which it is not), we would see a second rLFA tunnel towards XRv14. The number of this tunnel changes every time the protected link flaps, because after CSR1 converges and uses the real LSP, the rLFA tunnel is torn down as it is not needed.

```
CSR1#show ip ospf rib 2.2.2.2 255.255.255.255
[snip]
*> 2.2.2.2/32, Intra, cost 2, area 0
    SPF Instance 52, age 00:28:45
    Flags: RIB, HiPrio
    via 12.0.0.2, GigabitEthernet2.512
    Flags: RIB
    LSA: 1/2.2.2.2/2.2.2.2
    repair path via 13.13.13.13, MPLS-Remote-Lfa1, cost 4
    Flags: RIB, Repair, IntfDj, BcastDj
    LSA: 1/2.2.2.2/2.2.2.2
```

You can see some extra tunnel details which helps define the path. This shows XRv13 as the tail-end (PQ-node) with CSR4 being the first hop in the tunnel's path.

```
CSR1#show ip ospf fast-reroute remote-lfa tunnels
Interface MPLS-Remote-Lfa1
Tunnel type: MPLS-LDP
Tailend router ID: 13.13.13.13
Termination IP address: 13.13.13.13
Outgoing interface: GigabitEthernet2.514
First hop gateway: 14.0.0.4
Tunnel metric: 2
Protects:
    12.0.0.2 GigabitEthernet2.512, total metric 4
```

BFD must be configured for rLFA to work. The control-plane is fully operational without it as verified above, but you must use BFD. IGP fast hellos will not work, regardless of how fast they are, and BFD will work, no matter how slow it is. Thus, BFD has been enabled and bound to OSPF on the link between CSR1 and CSR2 (basic BFD configuration not shown). The "FRR" registered protocol represents LFA. Cisco suggests BFD is requirement for direct LFA as well, which makes sense.

```
CSR1#show bfd neighbors details | include 12.0.0.2|Register
12.0.0.2                4097/4097        Up        Up        Gi2.512
Registered protocols: OSPF CEF FRR
```

I added a quick Flexible Netflow (FNF) configuration to CSR4 to track incoming MPLS packets. This way, we can visualize CSR1 sending MPLS-encapsulated backup traffic through the rLFA tunnel.

```
! CSR4
flow record FNF_MPLS_RECORD
 match mpls label 1 details
 match mpls label 2 details
 collect counter packets

flow monitor FNF_MPLS_MONITOR
 record FNF_MPLS_RECORD

interface GigabitEthernet2.514
 mpls flow monitor FNF_MPLS_MONITOR input
```

The output below is showing the targeted LDP messages being sent from CSR1 to XRv13 (notice the label value of 4004 with EXP 6). This is just a basic TCP session between CSR1 and XRv13. This isn't relevant for rLFA, but we use it to verify that FNF was configured correctly.

```
CSR4#show flow monitor FNF_MPLS_MONITOR cache format table | begin MPLS
MPLS LABEL 1  MPLS LABEL 2      pkts
=====
4004 /6      0 /0      118
```

Next, I send several pings from CSR1's loopback to CSR2's loopback with DSCP CS1 (for identification, just in case something else generates traffic behind the scenes), then break the protected link on CSR2. We expect to see some traffic (not many packets) with a label stack of {4004 93008} which is used to tunnel traffic inside the rLFA tunnel to XRv13 (4004), then use XRv13's label for 2.2.2.2/32 to reach the final destination (93008). After OSPF converges, CSR1 uses the ordinary LDP-derived LSP via CSR4's label for 2.2.2.2/32 (4002). Tunneled rLFA traffic counters are shown in green and native forwarding through CSR4, after IGP convergence, is shown in yellow.

```
CSR1#ping 2.2.2.2 source loopback0 tos 32 repeat 100000000
```

```
! CSR2
interface GigabitEthernet2.512
 shutdown
```

```
CSR4#show flow monitor FNF_MPLS_MONITOR cache format table | begin MPLS
MPLS LABEL 1  MPLS LABEL 2      pkts
=====
4002 /1      0 /0      242
4004 /1      93008 /1      128
4004 /6      0 /0      18
```

```
CSR4#show flow monitor FNF_MPLS_MONITOR cache format table | begin MPLS
```

MPLS LABEL 1		MPLS LABEL 2		pkts
=====		=====		=====
4002	/1	0	/0	267
4004	/1	93008	/1	128
4004	/6	0	/0	18

In summary, the traffic with label stack {4004 93008} was inside the rLFA tunnel and was used for only the amount of time it took CSR1 to reconverge (I did not tune OSPF timers for ultra-fast convergence). Notice the difference in packet counters between the two FNF show commands; the rLFA stopped forwarding after 128 packets and the label stack {4002} was used thereafter as this was the post-SPF LSP. I highlighted the packet counters in different colors above so you can see that rLFA counters stop while the normal LSP counters continue to increase. We don't need to trace all the LSPs as the FNF output reveals the key behavioral components of this feature.

When we have a ring topology with an even number of nodes greater than 3, remote LFA becomes a little more complicated. CSR1 is removed from the network and CSR4's link to XRv13 is restored, making a square.

Given what we know about P and Q spaces, assuming we want to protect the link between CSR4 and CSR5, there is no traditional PQ-node. Without a PQ-node, it seems that remote LFA cannot work. The reason this seems to be the case is because CSR4's route to XRv14 is via an ECMP path-split between XRv13 and CSR5, which means XRv14 is not in CSR4's P-space. Additionally, because XRv13's route to CSR5 is via ECMP also, it is not part of CSR5's Q-space.

```
CSR4#show ip cef 14.14.14.14 | include _nexthop
  nexthop 34.0.0.13 GigabitEthernet2.534 label [93015|5004]
  nexthop 45.0.0.5 GigabitEthernet2.545 label [5004|93015]
```

```
RP/0/0/CPU0:XRv13#show cef ipv4 5.5.5.5/32 | include next hop
  next hop 34.0.0.4
  next hop 43.0.0.14
```

In order for rLFA to work, XRV14 needs to be in CSR4's P-space or XRV13 needs to be in CSR5's Q-space. This problem is solved by leveraging the "extended P-space" which makes the first condition somewhat true. The logic is as follows: CSR4 will only use the repair path when the direct link to CSR5 is down. This initial hop does not need to be subject to CSR4's normal routing process; this effectively allows us to relax the "you can't use ECMP" rule. The extended P-space is the union (combination) of the P-spaces of the source router (CSR4) and all of its P-space neighbors (XRV13). In terms of cost, a router is in the extended P-space if the cost XRV13->XRV14 is less than the cost XRV13->CSR4->CSR5->XRV14 ($1 < 3$). Basically, your neighbor (XRV13) has to be closer to the target PQ-node. In this case, XRV14 is within XRV13's P-space since it is reachable without using the protected link and is closer than CSR4 (downstream); XRV14 is in CSR4's extended P-space and is thus the PQ-node.

Fortunately, there is nothing special you have to configure for this advanced feature to work. Just enable the rLFA feature and the router "figures it out". We should see an rLFA tunnel from CSR4 to XRV14. In earlier examples we did not have LDP targeted session acceptance configured on XRV14 for demonstration purposes, so we must add it.

```

! XRv14
mpls ldp
  address-family ipv4
    discovery targeted-hello accept

```

I've also set up BFD and bound OSPF to it on the link between CSR4 and CSR5; remember that this is a requirement for rLFA to work. CSR4 actually builds two tunnels, one via CSR5 and one via XR13. Since our current objective is protecting the link to CSR5, we will ignore the second tunnel. Both of them terminate on XRv14 since it would be the PQ-node in either direction. Since XRv doesn't support BFD, we test link failures between CSR4 and CSR5 only.

```

CSR4#show ip ospf fast-reroute remote-lfa tunnels
[snip]
Interface MPLS-Remote-Lfa5
  Tunnel type: MPLS-LDP
  Tailend router ID: 14.14.14.14
  Termination IP address: 14.14.14.14
  Outgoing interface: GigabitEthernet2.534
  First hop gateway: 34.0.0.13
  Tunnel metric: 2
  Protects:
    45.0.0.5 GigabitEthernet2.545, total metric 3
[snip]

```

Performing a similar test as before, we send pings from CSR4 to CSR5, break the direct link, and ensure XRv13 sees the proper rLFA label stack. CSR4 learns label 94003 for the prefix 5.5.5.5/32 from XRv14 via tLDP. This will be the bottom label in the rLFA tunnel stack. CSR4 also needs a label for XRv14's loopback, the tunnel tail end. Because the route to 14.14.14.14/32 is IGP learned, an LDP label must be used, and XRv13 advertises label 93015. We expect the rLFA tunnel to use label stack {93015 94003} to tunnel traffic first to XRv14, then use XRv14's label for CSR5's loopback to deliver the traffic. When OSPF converges, we should use XRv13's LDP label for CSR5's loopback, which is 93002.

```

CSR4#show mpls ldp bindings 5.5.5.5 32
  lib entry: 5.5.5.5/32, rev 41
    local binding:  label: 4001
    remote binding: lsr: 5.5.5.5:0, label: imp-null
    remote binding: lsr: 13.13.13.13:0, label: 93002
    remote binding: lsr: 14.14.14.14:0, label: 94003

CSR4#show mpls ldp bindings 14.14.14.14 32
  lib entry: 14.14.14.14/32, rev 14
    local binding:  label: 4003
    remote binding: lsr: 13.13.13.13:0, label: 93015
    remote binding: lsr: 5.5.5.5:0, label: 5004
    remote binding: lsr: 14.14.14.14:0, label: imp-null

```

FNF does not appear to be supported on XRv, so we will use MPLS packet debugging, which does work. The XR debugs for this are extremely detailed; we will send these logs to the buffer only. We expect to see a short burst of traffic with label stack {93015 94003} with all follow-on traffic using label 93002. Like last time, we use MPLS EXP1 to differentiate the traffic against other potential flows, enhancing readability.

```
XRv13#debug mpls packet
```

```
CSR4#ping 5.5.5.5 source loopback0 tos 32 repeat 100000000
```

```
! CSR5
interface GigabitEthernet2.545
 shutdown
```

Here is debug output from XRv13 that shows traffic coming in with label 93015, which is XRv13's label for XRv14's loopback. We assume this is the rLFA tunnel because of the EXP bits being set to 1 and the label values appear correct. The LFIB states PHP should occur, so only label 94003 should go out towards XRv14. Notice that the packet length is 130 bytes on ingress.

```
! XRv13
mpls_switch: FINT0_0_CPU0, mpls eos 0, ttl 254, len 130, inlabel 93015,
tbl_id=0xe0000000, vrf_id=0x60000000 in=0xb00
mpls_rewrite
mpls_rewrite: tos 32 eos 0 ttl 254, out_label 1048577, #labels 0, RA - 0,
out_intf GigabitEthernet0_0_0.543
mpls_rewrite: POP to mpls
mpls_rewrite: tos 1 (0x1) eos 1 ttl 254, out_label 94003, top_of_stack
0x16f333fe
```

```
RP/0/0/CPU0:XRv13#show mpls forwarding labels 93015
```

Local Label	Outgoing Label	Prefix or ID	Outgoing Interface	Next Hop	Bytes Switched
93015	Pop	14.14.14.14/32	Gi0/0/0/0.543	43.0.0.14	1665321

A few seconds later, OSPF converges and XRv13 only sees traffic using label 93002 to reach CSR5's loopback as the rLFA tunnel is torn down. Notice the packet length is also 4 bytes less (126 vs. 130) than it was when using rLFA as the label stack contains one label, not two. XRv13 performs a label swap, not a pop, to send this traffic towards CSR5 via XRv14. The debug earlier clearly showed "POP to mpls" where this debug does not.

```
! XRv13
mpls_switch-2: Setting default table-id
Flag set to 0x00000001
mpls_switch: FINT0_0_CPU0, mpls eos 1, ttl 254, len 126, inlabel 93002,
tbl_id=0xe0000000, vrf_id=0x60000000 in=0xb00
```

```

mpls_rewrite
mpls_rewrite: tos 32 eos 1 ttl 254, out_label 94003, #labels 1, RA - 0,
out_intf GigabitEthernet0_0_0_0.543
mpls_rewrite: tos 1 (0x1) eos 1 ttl 254, out_label 94003, top_of_stack
0x16f333fe

```

Because BFD is not supported on XRv, we will not test the data plane of rLFA, but instead will verify control plane signaling when the rLFA tunnel headend is on XRv. Using the same square topology, we enable rLFA on XRv13 to protect the link to XRv14. On CSR5, we will configure LDP to accept targeted hellos as XRv13 must learn CSR5's label for XRv14.

```

! XRv13
router ospf 1
  fast-reroute per-prefix remote-lfa tunnel mpls-ldp
  fast-reroute per-prefix remote-lfa maximum-cost 20

! CSR5
mpls ldp discovery targeted-hello accept

```

To verify that we learn the label, we can check the LDP bindings to discover the value 5004. This is the bottom label in the rLFA tunnel. The top label is CSR4's label for CSR5, which is 4001. Thus, the rLFA tunnel encapsulation is {4001 5004}.

```

RP/0/0/CPU0:XRv13#show mpls ldp bindings 14.14.14.14/32 neighbor 5.5.5.5

```

Just for extra XR rLFA verification/practice, we will repeat the exercise to trace the LSP protecting the link between XRv13 and CSR4. Remember that XRv13 will build two tunnels to its PQ-node: one protects the link to XRv14 and one protects the link to CSR4. First we check the label bindings from LDP, then the OSPF RIB, then the FIB. We see that the label stack {94003 5002} contains two labels: the bottom label is 5002 which represents CSR5's label for 4.4.4.4/32, while the top label is 94003 which represents XRv14's label for 5.5.5.5/32. The RIB shows us the protected routing information and the FIB shows us the full label stack.

We will do one more test with XRV rLFA with OSPF for practice. We will revert to the pentagon topology for this, which means the router does not need to invoke an extended P-space calculation. **Note: Unlike IS-IS, we do not have the capability to filter rLFA targets by RID, but we can enable the process globally versus having to do it on every interface.** This should confirm that we have an LDP neighbor with CSR1, along with some new labels. The rLFA tunnel to CSR1 allows XRv13 to protect the path to XRv14's loopback, which is normally reachable via a direct link.

```
RP/0/0/CPU0:XRv13#show ospf route 14.14.14.14/32 backup-path

1.1.1.1 12.0.0.1 14.0.0.1

IPv6: (0)

We now learn CSR1's label for 14.14.14.14/32 which is 1007. This is the bottom label in the rLFA tunnel stack. The top label is whatever CSR4's label is for 1.1.1.1/32 (the rLFA endpoint), which is 4000. Thus, the rLFA label stack is {4000 1007}. After OSPF converges, XRv13 will use label 4004 to reach XRv14's loopback as this is the ordinary LDP LSP, using labels learned from the IGP nexthop (CSR4).

37.1.2 IS-IS

37.1.2.1 Direct LFA

The LFA topology for IS-IS is identical to the one used for OSPF, except we set the OSPF AD to 255 to remove its routes from the RIB. The LFA process is very similar between OSPF and IS-IS so this test will focus on the differences. The diagram is shown again below.

General notes:

- On XE, IPv6 LFA for OSPFv3 and IS-IS both appear unsupported. Although the configuration is generic to the IS-IS process and not to an AF, the IS-IS IPv6 RIB doesn't show LFA paths.
- IS-IS does not have a concept of "broadcast interface disjoint", so that isn't a tiebreaker.
- When you enable LFA in XE, you must select an IS-IS level, unlike OSPF where the area is optional. In XR, the level is optional.
- IS-IS does not appear to have a show command to list the tie-breaker sequence.
- IS-IS considers loopbacks (/32) to be "medium" priority by default.

Like the OSPFv2 direct LFA test, I've increased CSR1's metric on the LAN to CSR2/XRv13 and the P2P link to CSR4 to 15. CSR1 prefers the P2P path via CSR2 to reach XRv14's loopback, 14.14.14.14/32. The repair path via XRv13 is downstream (XRv13 is closer to XRv14 than CSR1 is), node-protecting (we don't go through CSR2 on the repair-path), and SRLG-disjoint (no SRLGs configured yet).

```

! CSR1
interface GigabitEthernet2.513
 isis metric 15

interface GigabitEthernet2.514
 isis metric 15

```

```

CSR1#show isis rib 14.14.14.14
IPv4 local RIB for IS-IS process 1
IPv4 unicast topology base (TID 0, TOPOID 0x0) =====
Repair path attributes:
    DS - Downstream, LC - Linecard-Disjoint, NP - Node-Protecting
    PP - Primary-Path, SR - SRLG-Disjoint

Routes under majornet 14.0.0.0/8:

14.14.14.14/32
  [115/L2/20] via 12.0.0.2(GigabitEthernet2.512), from 14.14.14.14, tag 0, LSP[6/25]
              (installed)
    repair path: 123.0.0.13(GigabitEthernet2.513) metric:25 (DS,NP,SR) LSP[3]
  [115/L2/25] via 123.0.0.13(GigabitEthernet2.513), from 13.13.13.13, tag 0, LSP[3/28]

```

If we remove XRv13 by shutting down its LAN interface, CSR1 will install the repair path via CSR2 through the LAN, but it is not longer node-protecting since we rely on CSR2 for primary and repair paths. This is less ideal and is the reason IS-IS picked the XRv13 repair path over the CSR2 repair path in the first place. Notice the extra path via CSR4 at the bottom; this is like an "ignored" but valid backup path.

```

! XRv13
interface GigabitEthernet0/0/0/0.513
 shutdown

CSR1#show isis rib 14.14.14.14 | begin 14\.14
14.14.14.14/32
  [115/L2/20] via 12.0.0.2(GigabitEthernet2.512), from 14.14.14.14, tag 0, LSP[6/28]
              (installed)
    repair path: 123.0.0.2(GigabitEthernet2.513) metric:25 (DS,SR) LSP[6]
  [115/L2/35] via 14.0.0.4(GigabitEthernet2.514), from 13.13.13.13, tag 0, LSP[3/31]

```

Let's force the backup path to use CSR4 versus CSR2 or XRv13. We bring XRv13 back into the network and set SRLGs on CSR1's interface to CSR2 (P2P) and LAN. Now, the backup path through CSR4 is preferred due to the SRLG being disjoint. Node-protection is achieved since CSR2 is not in CSR4's path to XRv14. Notice that CSR4 is not downstream when compared to CSR1 since both of their metrics to XRv14 are 20.

```

! CSR1
interface GigabitEthernet2.512
 srlg gid 222

interface GigabitEthernet2.513
 srlg gid 222

! XRv13
interface GigabitEthernet0/0/0/0.513
 no shutdown

```

```

CSR1#show isis rib 14.14.14.14 | begin 14\.14
14.14.14.14/32
  [115/L2/20] via 12.0.0.2(GigabitEthernet2.512), from 14.14.14.14, tag 0, LSP[6/29]
              (installed)
              repair path: 14.0.0.4(GigabitEthernet2.514) metric:35 (NP,SR) LSP[3]
  [115/L2/25] via 123.0.0.13(GigabitEthernet2.513), from 13.13.13.13, tag 0, LSP[3/32]

```

The next example changes CSR1's interface costs again and removes the SRLGs. The P2P link to CSR2 is changed to 15 and the LAN remains 15, while the cost to CSR4 is set to 10. We have three-way ECMP but one of the paths (via XRv13 LAN) is listed as a backup for the CSR P2P link path. We see a new option, primary-path, which indicates that the repair-path is also an ECMP path already used for forwarding.

```

! CSR1
interface GigabitEthernet2.512
  isis metric 15
  no srlg gid 222

interface GigabitEthernet2.513
  no srlg gid 222

interface GigabitEthernet2.514
  isis metric 10

```

```

CSR1#show isis rib 14.14.14.14 | begin 14\.14
14.14.14.14/32
  [115/L2/25] via 123.0.0.13(GigabitEthernet2.513), from 13.13.13.13, tag 0, LSP[4/42]
              (installed)
  [115/L2/25] via 123.0.0.13(GigabitEthernet2.513), from 14.14.14.14, tag 0, LSP[3/42]
  [115/L2/25] via 12.0.0.2(GigabitEthernet2.512), from 14.14.14.14, tag 0, LSP[3/42]
              (installed)
              repair path: 123.0.0.13(GigabitEthernet2.513) metric:25 (PP,DS,NP,SR) LSP[3]
  [115/L2/25] via 123.0.0.2(GigabitEthernet2.513), from 14.14.14.14, tag 0, LSP[3/42]
              (installed)

```

We can also check the repair path to CSR5 from here. CSR1 should prefer CSR4 based on lowest metric but uses the P2P path via CSR2 as a repair-path. CSR2 is not downstream since both routers have a metric of 20 to reach 5.5.5.5/32, but it is outside of the primary path (node protecting) and does not share an SRLG.

```

CSR1#show isis rib 5.5.5.5 | begin 5\.5
5.5.5.5/32
  [115/L2/20] via 14.0.0.4(GigabitEthernet2.514), from 5.5.5.5, tag 0, LSP[5/39]
              (installed)
              repair path: 12.0.0.2(GigabitEthernet2.512) metric:35 (NP,SR) LSP[5]

```

Shutting down CSR2's P2P link to CSR1 forces the repair path through the CSR2 LAN hop. Considering the attributes of this path are identical to those of the P2P link, I am assuming IS-IS prefers P2P over multi-

access links. Cisco mentions LFA doesn't work on IS-IS broadcast networks, but this might be a hardware-based limitation since the control-plane has shown multi-access-facing LFAs in earlier tests.

```
CSR1#show isis rib 5.5.5.5 | begin 5\.5
5.5.5.5/32
  [115/L2/20] via 14.0.0.4(GigabitEthernet2.514), from 5.5.5.5, tag 0, LSP[5/41]
              (installed)
              repair path: 123.0.0.2(GigabitEthernet2.513) metric:35 (NP,SR) LSP[5]
```

Completely removing CSR2 from the network, CSR1 now prefers XRv3 via the LAN. This is less preferable because it does not offer node protection as XRv13 has an ECMP path to CSR5 that routes through CSR4.

```
! CSR2
interface GigabitEthernet2
 shutdown

CSR1#show isis rib 5.5.5.5 | begin 5\.5
5.5.5.5/32
  [115/L2/20] via 14.0.0.4(GigabitEthernet2.514), from 5.5.5.5, tag 0, LSP[5/40]
              (installed)
              repair path: 123.0.0.13(GigabitEthernet2.513) metric:35 (SR) LSP[5]
```

Of course, we can change XRv13's costs so that it prefers to route through XRv14 to reach CSR5. Reducing the metric on the XRv13 link facing XRv14 to 5 should force traffic through XRv14 only. We should achieve node protection (and downstream status) for this backup path now. The metric reduction from 35 to 30 also shows as the backup path's cost follows XRv13's best path through XRv14. In summary, IS-IS LFA behaves almost identically to OSPF LFA.

```
! XRv13
router isis 1
 interface GigabitEthernet0/0/0/0.534
   address-family ipv4 unicast
   metric 5

CSR1#show isis rib 5.5.5.5 | begin 5\.5
5.5.5.5/32
  [115/L2/20] via 14.0.0.4(GigabitEthernet2.514), from 5.5.5.5, tag 0, LSP[13/17]
              (installed)
              repair path: 123.0.0.13(GigabitEthernet2.513) metric:30 (DS,NP,SR) LSP[13]
```

Next, we quickly examine direct LFA on IOS-XR. Both IPv4 and IPv6 are supported, which is an improvement over XE. I have enabled LFA for both AFs on XRv13 but IPv6 will be analyzed later. The configuration is highly redundant since the feature must be enabled under each interface per-AFI.

```
! XRv13
router isis 1
 interface GigabitEthernet0/0/0/0.513
```

```

address-family ipv4 unicast
  fast-reroute per-prefix

interface GigabitEthernet0/0/0/0.534
  address-family ipv4 unicast
    fast-reroute per-prefix
  address-family ipv6 unicast
    fast-reroute per-prefix

interface GigabitEthernet0/0/0/0.543
  address-family ipv4 unicast
    fast-reroute per-prefix
  address-family ipv6 unicast
    fast-reroute per-prefix

```

Earlier we changed the IPv4 metrics so that XRv13 routes via XRv14 to reach 5.5.5.5/32. It now has an LFA via CSR4; the "detail" keyword lets us see which path attributes apply. This path is not a primary-path (P), total metric is 20 (TM), is not linecard disjoint (LC), is node protecting (NP), is downstream (D), and is SRLG disjoint. The "SRLG: Yes" phrase is confusing because XR is really saying "SRLG is absent", not "SRLG is present". The output also shows us that the default prefix-priority of this loopback is medium, not high like XE. Default tie-breakers for XR IS-IS LFA are as follows. Notice that SRLG is not considered by default.

10 Primary path

20 Lowest metric

30 Line card disjoint

40 Node protection

```

RP/0/0/CPU0:XRv13#show isis ipv4 fast-reroute 5.5.5.5/32 detail
L2 5.5.5.5/32 [15/115] medium priority
   via 43.0.0.14, GigabitEthernet0/0/0/0.543, XRv14, Weight: 0
   FRR backup via 34.0.0.4, GigabitEthernet0/0/0/0.534, CSR4, Weight: 0
   P: No, TM: 20, LC: No, NP: Yes, D: Yes, SRLG: Yes
src CSR5.00-00, 5.5.5.5

```

Next, we will use SRLG to see if we can select the path through CSR1 instead of CSR4. Below is the SRLG configuration. XR SRLG configuration is nice because you can use descriptive names or values. We also have to tell IS-IS to use the SRLG in its computations. I also adjust SRLG to be the most important tie-breaker for IS-IS LFA, which is specific to level-2.

```

! XRv13
srlg
  name SAME_FIBER_PAIR value 134
interface GigabitEthernet0/0/0/0.534

```

```

name SAME_FIBER_PAIR

interface GigabitEthernet0/0/0/0.543
name SAME_FIBER_PAIR

router isis 1
address-family ipv4 unicast
fast-reroute per-prefix tiebreaker srlg-disjoint index 1 level 2

```

Now, the LFA is via CSR1, which is not downstream (CSR1 cost is 20, XRv13 is 15), but is node protecting and SRLG disjoint.

```

RP/0/0/CPU0:XRv13#show isis fast-reroute 5.5.5.5/32 detail

L2 5.5.5.5/32 [15/115] medium priority
  via 43.0.0.14, GigabitEthernet0/0/0/0.543, XRv14, Weight: 0
  FRR backup via 123.0.0.1, GigabitEthernet0/0/0/0.513, CSR1, Weight: 0
    P: No, TM: 30, LC: No, NP: Yes, D: No, SRLG: Yes
src CSR5.00-00, 5.5.5.5

```

Last, we modify the IS-IS path selection to make lowest-metric the most important tie-breaker with SRLG as the second most important. The original backup path via CSR4 should be preferred since its total metric is lower (20 versus 30), but notice that this path is not SRLG disjoint. As a reminder, the text “SRLG: No” indicates that the SRLG is present and the LFA is not SRLG-disjoint.

```

! XRv13
router isis 1
address-family ipv4 unicast
fast-reroute per-prefix tiebreaker lowest-backup-metric index 1 level 2

    P: No, TM: 20, LC: No, NP: Yes, D: Yes, SRLG: No
src CSR5.00-00, 5.5.5.5

```

In summary, direct (or local) LFA is very similar between IS-IS and OSPF, also between XE and XR. The exact tiebreakers and their sequential arrangements vary slightly between platforms and protocols.

37.1.2.2 Remote LFA

Remote LFA (rLFA) for IS-IS is very similar to OSPF. We still require MPLS encapsulation with LDP signaling regardless of the IGP in play. Because the mechanics of rLFA (P-space, extended P-space, Q-space, and PQ-nodes) were discussed already, it is not discussed again because the concepts are the same. The testing below just demonstrates the feature using IS-IS. We will use the same pentagon

topology as we used in OSPF, ensuring that we bind IS-IS to BFD on that P2P link between CSR1 and CSR2. All interfaces have IS-IS metric of 10. For brevity we will not demonstrate the square topology as the configuration and verification is identical.

A quick verification of BFD is in order because **without BFD, LFA data-plane operations do not work**. This test is targeting the CSR1-CSR2 link as the protected link, so ensuring BFD is enabled on that link is a good first step.

```
CSR1#show bfd neighbors client isis
IPv4 Sessions
NeighAddr                LD/RD                RH/RS                State                Int
12.0.0.2                4097/4097                Up                Up                Gi2.512
```

We enable rLFA on CSR1 under the IS-IS process. We must specify an IS-IS level, which is different than OSPF. In OSPF, we could optionally specify an area, and failing to specify an area would protect all areas as well as external routes. IS-IS is less generic and requires the rLFA feature specified for each level. The output below is very terse and there is no "detail" option, but gives quick insight. We don't really care about Lfa24 because we are trying to protect the link to CSR2, which implies an rLFA tunnel to XRv13. If we were trying to protect the link to CSR4, the rLFA tunnel to XRv14 would matter.

```
! CSR1
router isis 1
 fast-reroute remote-lfa level-2 mpls-ldp maximum-metric 20
```

```
CSR1#show isis fast-reroute remote-lfa tunnels
Tag 1 - Fast-Reroute Remote-LFA Tunnels:
 MPLS-Remote-Lfa23: use Gi2.514, nexthop 14.0.0.4, end point 13.13.13.13
 MPLS-Remote-Lfa24: use Gi2.512, nexthop 12.0.0.2, end point 14.14.14.14
```

We should verify that we have an LDP neighbor with the PQ-node, XRv13, and that we learn its LDP local-label for 2.2.2.2/32. This prefix is the final destination that we are trying to protect. Forming an LDP session with XRv13 assumes that XRv13 is accepting tLDP sessions from CSR1 (configured earlier). The bottom label in the rLFA tunnel will be 93003. Also note that label 4007 will be used for normal forwarding once the rLFA tunnel is torn down after IS-IS reconverges. The top label is the rLFA tunnel endpoint, which is towards 13.13.13.13/32; the label value is learned by CSR4 with a label of 4001.

```

```

We still have MPLS FNF configured on CSR4 facing CSR1 from the OSPF tests. When we send traffic from CSR1 to CSR2's loopback, then break the P2P link between them (breakage not shown), we see a short burst of traffic with label stack {4001 93003} which is rLFA-encapsulated traffic shown in green. Traffic with label 4007 is used thereafter for normal forwarding when IS-IS converges, shown in yellow. Notice that after 119 packets, the rLFA is no longer used, and the traffic uses the regular LDP signaled LSP for transport.

```

4001	/1	93003	/1	119

Because BFD is not supported on XRv, we will limit our rLFA tests to control-plane verifications. We will enable rLFA on XRv13 to protect the path to 14.14.14.14/32 (protect the link between XRv13 and XRv14). rLFA for IS-IS in XR is enabled at the link-level; the AF-level command is used to filter PQ-node candidacy based on RID with a prefix-list. I added this filter to the configuration just to test the feature; I don't care about backing up the path to 4.4.4.4/32 so I do not need an rLFA tunnel to CSR2 for this test, only CSR1. This can help scale rLFA since building too many tunnels to protect links unnecessarily may resource-intensive.

```

! XRv13
ipv4 prefix-list PL_CSR1
10 permit 1.1.1.1/32

router isis 1
address-family ipv4 unicast
fast-reroute per-prefix remote-lfa prefix-list PL_CSR1

```

```

interface GigabitEthernet0/0/0/0.513
  address-family ipv4 unicast
    fast-reroute per-prefix remote-lfa tunnel mpls-ldp level 2
    fast-reroute per-prefix remote-lfa maximum-metric 20

interface GigabitEthernet0/0/0/0.534
  address-family ipv4 unicast
    fast-reroute per-prefix remote-lfa tunnel mpls-ldp level 2
    fast-reroute per-prefix remote-lfa maximum-metric 20

interface GigabitEthernet0/0/0/0.543
  address-family ipv4 unicast
    fast-reroute per-prefix remote-lfa tunnel mpls-ldp level 2
    fast-reroute per-prefix remote-lfa maximum-metric 20

```

The output below shows that XRv14's loopback is backed up by an rLFA tunnel terminating on CSR1. Notice that the total metric (TM) is the cost to the tunnel endpoint, not the entire path.

```

Next, we determine the label stacks required if this rLFA tunnel were to be used. We learn CSR1's label for XRv14's loopback is 1007 which would be the bottom label in the rLFA stack. Label 4004 would be the post-IGP convergence label we would use after the rLFA tunnel is no longer needed. Last, we need to know the transport label to reach the rLFA tunnel endpoint, which is 1.1.1.1/32. We have label 4000

from CSR4 that directs us there. The rLFA stack would be {4000 1007} and the label used after IS-IS converges is 4004.

37.1.3 EIGRP

EIGRP LFA is the simplest topic in this section. All EIGRP LFA does is take feasible successors and pre-install them into the FIB for slightly faster convergence. EIGRP is not actually doing more work than it used to, and only feasible successor (FS) paths are candidates for FRR. After all, they are guaranteed to be LFAs already, unlike OSPF and IS-IS which required additional logic. This implies that all EIGRP LFA paths must be downstream; in OSPF and IS-IS we saw that backup paths did not need to be downstream because the link-state nature of those protocols could run SPF as their neighbors. EIGRP does not have that intelligence, so meeting the feasibility condition (which is effectively mandating “downstream”) is required. In a virtual platform, EIGRP LFA probably does not have a significant performance impact since there are not hardware linecards or TCAM components to program. We will use the same topology we used earlier for EIGRP FRR with IPv4. IPv6 does not appear supported at this time, nor is there a concept of remote LFA in EIGRP. EIGRP LFA is also not supported in XR. As a result, the EIGRP FRR options are much less comprehensive than OSPF and IS-IS. For this test, only interface delay is considered, which effectively allows us to mimic IS-IS and OSPF path selection mechanisms; using bandwidth makes the EIGRP calculation more complicated since it's evaluated per-path, not per-hop.

We will begin by evaluating CSR5's route to XRV13 with metric modifications. With FRR enabled in OSPF or IS-IS, we expect two ECMP paths via CSR4 and XRV14, each of which backs the other one up. In EIGRP, this concept does not apply, and we only see the two ECMP paths as we normally would. This is acceptable since the paths are both installed in the FIB anyway (primary paths used for ECMP), so EIGRP need not identify them as mutually-supporting LFAs.

```

! CSR5
router eigrp LFA_TEST
 address-family ipv4 unicast autonomous-system 1
   topology base
     fast-reroute per-prefix all

```

```

CSR5#show eigrp address-family ipv4 topology frr | section 13\.13
P 13.13.13.13/32, 2 successors, FD is 3997696
  via 45.0.0.4 (3997696/720896), GigabitEthernet2.545
  via 54.0.0.14 (3997696/720896), GigabitEthernet2.554

```

Increasing the delay on CSR5's link to XRV14 will allow CSR5 to prefer the path via CSR4 as primary. The path through XRV14 is an LFA because it is an EIGRP feasible successor (XRV14 is closer to XRV13 than CSR5 is, since $720896 < 3997696$). OSPF and IS-IS call this "downstream" which is a more generic term of expressing the feasibility condition in EIGRP (same concept).

```

CSR5#show eigrp address-family ipv4 topology frr | section 13\.13
P 13.13.13.13/32, 1 successors, FD is 3997696
  via 45.0.0.4 (3997696/720896), GigabitEthernet2.545

```

```
via 54.0.0.14 (7274496/720896), GigabitEthernet2.554, [LFA]
```

Next, we will set the delay of all EIGRP interfaces to 5 to make traffic engineering a little easier (not shown). Using EIGRP named-mode on XE displays the delay in picoseconds versus microseconds (ms was used in classic EIGRP). Note: A quick conversion from ps to ms is to trim the last 6 zeroes of the ps field. If we increase the delay value on XRv14's link to XRv13 to 10, then CSR5 and XRv14 are equidistant from XRv13. The EIGRP feasibility condition (or downstream condition) is not satisfied, and the alternate path via XRv14 path is not an LFA. OSPF and IS-IS are more intelligent, and given their link-state information they can still use non-downstream paths in some cases (unlike when FD = RD, which is 6619136 in this case). Here, we prove that EIGRP's FS condition remains inflexible despite the LFA feature.

```
CSR5#show eigrp address-family ipv4 topology frr | section 13\.13
P 13.13.13.13/32, 1 successors, FD is 3997696
    via 45.0.0.4 (6619136/3342336), GigabitEthernet2.545, serno 152
    via 54.0.0.14 (9895936/6619136), GigabitEthernet2.554
```

EIGRP also has a limited number of tie-breakers, such as interface-disjoint, linecard-disjoint, lowest metric, and SRLG-disjoint. We will test interface-disjoint as the tie-breaker since we have a LAN interface. We will use CSR1 for this demonstration as it has additional path diversity. All interfaces have been reset to delay 5 as a baseline. Initially, CSR1 does 3-way load sharing to XRv14's loopback via CSR2 LAN, CSR2 P2P, and XRv13 LAN. Changing XRv13's cost to XRv14 to 4 makes it the best path. However, rather than prefer CSR2 over the LAN, CSR1 prefers CSR2 via the P2P link to be interface-disjoint. The CSR2 LAN link is definitely a feasible successor (LFA) but was not preferred. Notice that CSR4 is not a candidate LFA because its RD equals CSR1's FD (5963776). Also note that we did not need to explicitly configure this tie-breaker since its enabled within EIGRP and cannot be disabled.

```
! XRv3
router eigrp LFA_TEST
 address-family ipv4
   interface GigabitEthernet0/0/0/0.543
     metric delay 4
```

```
CSR1#show eigrp address-family ipv4 topology frr | sec 14\.14
P 14.14.14.14/32, 1 successors, FD is 5963776
    via 123.0.0.13 (5963776/2686976), GigabitEthernet2.513
    via 12.0.0.2 (6619136/3342336), GigabitEthernet2.512, [LFA]
    via 123.0.0.2 (6619136/3342336), GigabitEthernet2.513
    via 14.0.0.4 (9240576/5963776), GigabitEthernet2.514
```

Increasing CSR1's cost on the CSR2 P2P link increases the metric to 14.14.14.14/32 via that link, but it's still the preferred LFA. In the previous example, both of these FS paths had the same FD, but the interface-disjoint characteristic served as the tie-breaker. This proves that interface-disjoint is a higher tie-breaker than lowest metric.

```

! CSR1
interface GigabitEthernet2.512
  delay 6

CSR1#show eigrp address-family ipv4 topology frr | sec 14\.14
P 14.14.14.14/32, 1 successors, FD is 5963776
  via 123.0.0.13 (5963776/2686976), GigabitEthernet2.513
  via 12.0.0.2 (7274496/3342336), GigabitEthernet2.512, [LFA]
  via 123.0.0.2 (6619136/3342336), GigabitEthernet2.513
  via 14.0.0.4 (9240576/5963776), GigabitEthernet2.514

```

When we configure lowest metric as the #1 tie-breaker, the LFA via CSR2 LAN is used. None of the metrics have changed, but the order in which tie-breakers are evaluated allowed us to select a new LFA. This tie-breaker prioritization process works identically to OSPF and IS-IS.

```

! CSR1
router eigrp LFA_TEST
  address-family ipv4 unicast autonomous-system 1
  topology base
  fast-reroute tie-break lowest-backup-path-metric 1

CSR1#show eigrp address-family ipv4 topology frr | sec 14\.14

  via 12.0.0.2 (7274496/3342336), GigabitEthernet2.512
  via 123.0.0.2 (6619136/3342336), GigabitEthernet2.513, [LFA]
  via 14.0.0.4 (9240576/5963776), GigabitEthernet2.514

```

Let's reset the network to baseline delays of 5 (not shown) and test the SRLG feature. The only noteworthy metric changes are CSR1's link to CSR4 has delay 2 and CSR4's link to CSR5 has delay 3. This allows CSR1 to do 4-way load sharing to XRv14 as all paths have a cumulative delay value of 11 (XRv4's loopback counts as delay 1).

```

! CSR1
interface GigabitEthernet2.514
  delay 2

! CSR4
interface GigabitEthernet2.545
  delay 3

CSR1#show ip eigrp topology frr | section 14\.14
P 14.14.14.14/32, 4 successors, FD is 5963776
  via 12.0.0.2 (6619136/3342336), GigabitEthernet2.512
  via 123.0.0.2 (6619136/3342336), GigabitEthernet2.513
  via 123.0.0.13 (6619136/3342336), GigabitEthernet2.513
  via 14.0.0.4 (6619136/5308416), GigabitEthernet2.514

```

We now reduce CSR1's delay to CSR2 on the P2P link to 4 so it becomes the best path, but there are three candidate LFAs all with equal cost. CSR1 selects XRv13 but the evaluation criteria for this decision is unclear. My initial guess is because XRv13 has the higher IP address.

```
! CSR1
interface GigabitEthernet2.512
  delay 4
```

```
CSR1#show ip eigrp topology frr | section 14\.14
P 14.14.14.14/32, 1 successors, FD is 5963776
    via 12.0.0.2 (5963776/3342336), GigabitEthernet2.512
    via 123.0.0.2 (6619136/3342336), GigabitEthernet2.513
    via 123.0.0.13 (6619136/3342336), GigabitEthernet2.513, [LFA]
    via 14.0.0.4 (6619136/5308416), GigabitEthernet2.514
```

Shutting down the LAN interface on XRv13 causes the router to pick CSR4. Despite having a lower IP address than 123.0.0.2, 14.0.0.4 was likely chosen due to offering node-protection, where 123.0.0.2 is the same router as 12.0.0.2 (successor path). Clearly the RD is not being evaluated since CSR4's is the highest, but this was never a criteria for LFA paths provided the RD < FD (meets feasibility condition). Node-protection is not a term used in the EIGRP LFA documentation anywhere, so I cannot prove that node-protection is even evaluated by EIGRP. Considering it does not have a concept of "nodes" (no corresponding graph structure), node-protection in EIGRP is unlikely nonexistent.

```
! XRv13
interface GigabitEthernet0/0/0/0.513
  shutdown
```

```
CSR1#show ip eigrp topology frr | section 14\.14
P 14.14.14.14/32, 1 successors, FD is 5963776
    via 12.0.0.2 (5963776/3342336), GigabitEthernet2.512
    via 123.0.0.2 (6619136/3342336), GigabitEthernet2.513
    via 14.0.0.4 (6619136/5308416), GigabitEthernet2.514, [LFA]
```

Using SRLG, let's assume we want the router to always pick CSR4 over the LAN interfaces if possible. We apply the same SRLG to the CSR2 P2P link and the LAN interface. We must manually assign SRLG to the EIGRP tie-break list because it is not assigned by default. This is similar to IS-IS, but different than OSPF where SRLG is evaluated by default. Below, we add it as the second tiebreaker (lowest metric was the first). We also bring XRv13 back into the LAN. Without this SRLG configuration, XRv13 would immediately become the preferred LFA again. Using SRLGs in this way allows us to semi-administratively select CSR4 as the preferred LFA.

```
! CSR1
interface GigabitEthernet2.512
  srlg gid 45
```

```

interface GigabitEthernet2.513
  srlg gid 45

router eigrp LFA_TEST
  address-family ipv4 unicast autonomous-system 1
  topology base
  fast-reroute tie-break srlg-disjoint 2

! XRV13
interface GigabitEthernet0/0/0/0.513
  no shutdown

CSR1#show ip eigrp topology frr | section 14\.14
P 14.14.14.14/32, 1 successors, FD is 5963776
  via 12.0.0.2 (5963776/3342336), GigabitEthernet2.512
  via 123.0.0.13 (6619136/3342336), GigabitEthernet2.513
  via 123.0.0.2 (6619136/3342336), GigabitEthernet2.513
  via 14.0.0.4 (6619136/5308416), GigabitEthernet2.514, [LFA]

```

We can override the SRLG by making the cost to CSR4 less desirable. We increase the delay from 2 to 3 on CSR1's P2P link to CSR4 and now XRV13 is preferred again. CSR4 is still an EIGRP FS, and therefore a candidate LFA, but is rejected since lowest backup metric is the #1 tie-breaker. This path violates the SRLG configuration; SRLG is the #2 tie-breaker so EIGRP doesn't even evaluate SRLG since the tie was already broken in the previous step.

```

37.2 Loop Free Alternate (LFA) for IPv6 (XR Only)

This feature only seems to be supported on XR currently. Remote LFA for IPv6 is going to require LDPv6 which supposedly came out in XR 5.3.0, which is newer than what the CCIE lab will use. We will examine it briefly for completeness since IPv6 is a major focus area of the CCIE SP exam.

37.2.1 OSPFv3

37.2.1.1 Direct LFA

We will evaluate using direct LFA with OSPFv3 on XR. Be sure to adjust the administrative distances to make OSPF preferred over IS-IS if you were previously testing IS-IS. The network is shown again below for reference.

We will examine the network from XRV14's perspective for this test. We enable LFA under area 0 in per-prefix mode. Initially, there is a familiar situation with two ECMP paths that are backing each other up. These are ECMP paths from XRV14 to ::1:1:1:1/128, which is CSR1's IPv6 loopback prefix.

```

! XRV14
router ospfv3 1
 area 0
  fast-reroute per-prefix

```

```

RP/0/0/CPU0:XRV14#show ospfv3 routes ::1:1:1:1/128 backup-path

      Backup path:
        fe80::2, from 1.1.1.1, via GigabitEthernet0/0/0/0.524, protected
  bitmap 0x2

```

Attributes: Metric: 2, Primary, Downstream, Node Protect, SRLG Disjoint

For consistency, we recycle an old SRLG configuration on XRv14 to verify SRLGs work with OSPFv3. We then increase the OSPFv3 cost to XRv13 so that CSR2 is the primary with CSR5 as the backup. We also achieve node protection as CSR2 is not in the backup path. XRv13 is node-protecting also, but would violate the SRLG policy.

```
! XRv14
srlg
 interface GigabitEthernet0/0/0/0.524
   8 value 654

bitmap 0x1
  Attributes: Metric: 3, Node Protect, SRLG Disjoint
```

Rather than repeat the exact set of tests we did for IPv4, we will test new things. Next, we will examine XRv14's path to CSR4's loopback. Due to the cost modification, XRv14 routes through CSR5 with a backup via XRv13. This is SRLG disjoint and node-protecting as expected.

```
RP/0/0/CPU0:XRv14#show ospfv3 routes ::4:4:4:4/128 backup-path
Topology Table for OSPFv3 1 with ID 14.14.14.14
* ::4:4:4:4/128, Intra, cost 2/0, area 0
  GigabitEthernet0/0/0/0.554, fe80::5, path-id 1

bitmap 0x1
  Attributes: Metric: 3, Downstream, Node Protect, SRLG Disjoint
```

Before continuing, we remove our OSPFv3 cost modification so XRv14 performs ECMP back to CSR4 with the primary paths repairing one another (output not shown). We will test a new technology that also applies to IPv4 but was not evaluated earlier. This is the usage of "lfa-candidate" and "use-candidate-

only". The former is used to identify interfaces that are LFA candidate interfaces (that is, allowed to host LFA paths exiting them) and the second command forces LFAs to use only those interfaces explicitly identified as LFA candidates. It's like a stricter version of SRLG since we can hard-code candidate interfaces and for LFA to follow those constraints. The configuration below shows our LFA parameters. We want to use the link via CSR2 for LFAs if possible.

```
! XRv14
router ospfv3 1
  fast-reroute per-prefix lfa-candidate interface GigabitEthernet0/0/0/0.524
  fast-reroute per-prefix use-candidate-only enable
```

After applying these changes, we still have two ECMP paths, but both are backed up via CSR2. This makes sense since only that interface is able to host LFA paths. When using CSR5, the backup path is SRLG disjoint (the SRLG is on the CSR2 and XRv13 links) and node-protecting. When routing through XRv13, the backup path through CSR2 is neither SRLG disjoint nor node protecting, which would normally make it a relatively undesirable LFA.

```

      fe80::2, from 4.4.4.4, via GigabitEthernet0/0/0/0.524, protected
  bitmap 0x3
    Attributes: Metric: 3,
```

The reason the path is not node protecting is because CSR2 does 3-way ECMP between its two links to CSR1 and its link to XRv13. Thus, if the primary path from XRv14 to CSR4 routes through XRv13, we cannot guarantee node protection if we install an LFA via CSR2. Though LFA is configured locally, the resulting backup paths are highly dependent on the network views from the adjacency nodes.

```
CSR2#show ipv6 route ::4:4:4:4
Routing entry for ::4:4:4:4/128
  Known via "ospf 1", distance 110, metric 2, type intra area
  Backup from "isis 1 [115]"
  Route count is 3/3, share count 0
  Routing paths:

    FE80::13, GigabitEthernet2.513
      Last updated 00:00:00 ago
```

```
FE80::1, GigabitEthernet2.513
Last updated 00:00:00 ago
```

We can engineer node protection by forcing CSR2 not to use its LAN interface to reach CSR4 by increasing the OSPFv3 cost to 2. As soon as we do that, we achieve node protection, since the LFA path (via CSR2) does not rely on XRv13 for reachability to CSR4. Instead, CSR2 routes via CSR1 to reach CSR4, bypassing XRv13 entirely. This short series of tests proves that LFA is very similar between IPv4 and IPv6.

```

37.2.1.2 Remote LFA

Remote LFA does not appear to be supported for OSPFv3 (XR 5.3.0) at this time. This chapter is left here as a placeholder for completeness since I expect the feature to be supported soon.

37.2.2 IS-IS

37.2.2.1 Direct LFA

We will use XRv13 to reach CSR5's loopback for this demonstration. The diagram is shown again below for reference.

Enabling IS-IS LFA for IPv6 is identical to IPv4 and is done on a per-interface, per-AFI basis as shown below. Initially we see the ECMP paths backing each other up. Both CSR4 and XRV14 are downstream (closer to CSR5), node protecting, primary (ECMP) paths, equal metrics, and SRLG disjoint.

```

! XRV13
router isis 1
interface GigabitEthernet0/0/0/0.513
  address-family ipv6 unicast
  fast-reroute per-prefix

interface GigabitEthernet0/0/0/0.534
  address-family ipv6 unicast
  fast-reroute per-prefix

interface GigabitEthernet0/0/0/0.543
  address-family ipv6 unicast
  fast-reroute per-prefix
  
```

```

RP/0/0/CPU0:XRv13#show isis ipv6 fast-reroute ::5:5:5:5/128 detail
L2 ::5:5:5:5/128 [20/115] medium priority
  via fe80::14, GigabitEthernet0/0/0/0.543, XRv14, Weight: 0
    FRR backup via fe80::4, GigabitEthernet0/0/0/0.534, CSR4, Weight: 0
    P: Yes, TM: 20, LC: No, NP: Yes, D: Yes, SRLG: Yes
  via fe80::4, GigabitEthernet0/0/0/0.534, CSR4, Weight: 0
    FRR backup via fe80::14, GigabitEthernet0/0/0/0.543, XRv14, Weight: 0
    P: Yes, TM: 20, LC: No, NP: Yes, D: Yes, SRLG: Yes
src CSR5.00-00, ::5:5:5:5
  
```

We will increase XRv13's metric to XRv14 to 15 so that XRv13 prefers the path through CSR4 to ::5:5:5:5/128. We see the increase in total-metric (TM) to 25, and the path is no longer ECMP (primary, indicated by the "P" flag). We have introduced a strict primary/backup relationship between the CSR4/XRv14 paths after this metric adjustment.

```
! XRv13
router isis 1
 interface GigabitEthernet0/0/0/0.543
   address-family ipv6 unicast
   metric 15

RP/0/0/CPU0:XRv13#show isis ipv6 fast-reroute ::5:5:5:5/128 detail
L2 ::5:5:5:5/128 [20/115] medium priority
   via fe80::4, GigabitEthernet0/0/0/0.534, CSR4, Weight: 0
     FRR backup via fe80::14, GigabitEthernet0/0/0/0.543, XRv14, Weight: 0
     P: No, TM: 25, LC: No, NP: Yes, D: Yes, SRLG: Yes
   src CSR5.00-00, ::5:5:5:5
```

Next, we remove that metric adjustment and instead apply an SRLG to XRv13's links to CSR4 and XRv14. Notice that the SRLG disjoint attribute is removed but we still use it for the backup paths. This is because XR does not consider SRLGs by default; notice how the two paths back each other up as they did in the very first test.

```
! XRv13
srlg
 interface GigabitEthernet0/0/0/0.534
   8 value 333

 interface GigabitEthernet0/0/0/0.543
   8 value 333

router isis 1
 interface GigabitEthernet0/0/0/0.543
   address-family ipv6 unicast
   no metric

RP/0/0/CPU0:XRv13#show isis ipv6 fast-reroute ::5:5:5:5/128 detail
L2 ::5:5:5:5/128 [20/115] medium priority
   via fe80::14, GigabitEthernet0/0/0/0.543, XRv14, Weight: 0
     FRR backup via fe80::4, GigabitEthernet0/0/0/0.534, CSR4, Weight: 0
     P: Yes, TM: 20, LC: No, NP: Yes, D: Yes, SRLG: No
   via fe80::4, GigabitEthernet0/0/0/0.534, CSR4, Weight: 0
     FRR backup via fe80::14, GigabitEthernet0/0/0/0.543, XRv14, Weight: 0
     P: Yes, TM: 20, LC: No, NP: Yes, D: Yes, SRLG: No
   src CSR5.00-00, ::5:5:5:5
```

Next, we make SRLG the #1 tiebreaker. Now, XRv13 will prefer to not backup those ECMP paths with one another.

```
! XRv13
router isis 1
 address-family ipv6 unicast
  fast-reroute per-prefix tiebreaker srlg-disjoint index 1
```

XRv13 uses the paths through XRv14 and CSR4 for ECMP but backs them both up via CSR1. CSR1 is not downstream to CSR5 as XRv13 is closer, but when used to backup the XRv14 path only, node protection is achieved. Overall, it is a less desirable LFA, but since CSR4 and XRv4 “fate-share”, it makes sense to introduce a third link for better resiliency.

```
RP/0/0/CPU0:XRv13#show isis ipv6 fast-reroute ::5:5:5:5/128 detail
L2 ::5:5:5:5/128 [20/115] medium priority
  via fe80::14, GigabitEthernet0/0/0/0.543, XRv14, Weight: 0
    FRR backup via fe80::1, GigabitEthernet0/0/0/0.513, CSR1, Weight: 0
    P: No, TM: 30, LC: No, NP: Yes, D: No, SRLG: Yes
  via fe80::4, GigabitEthernet0/0/0/0.534, CSR4, Weight: 0
    FRR backup via fe80::1, GigabitEthernet0/0/0/0.513, CSR1, Weight: 0
    P: No, TM: 30, LC: No, NP: No, D: No, SRLG: Yes
src CSR5.00-00, ::5:5:5:5
```

The path from XRv13 to CSR2 is another candidate path but provides node protection for CSR4, not XRv14. It is functionally equivalent to the CSR1 path. By shutting down CSR1's LAN interface, the router selects CSR2. When CSR1 comes back online, XRv13 still prefers CSR2, and it appears to be similar to the eBGP tie-breaker of selecting the oldest route when all other tiebreakers are equal. Notice that node protection is achieved when backing up CSR4 but not XRv14. This is the opposite problem we saw above; there is one LFA protecting both primary paths when the second LFA is just as good.

```
! CSR1
interface GigabitEthernet2.513
 shutdown
```

```
RP/0/0/CPU0:XRv13#show isis ipv6 fast-reroute ::5:5:5:5/128 detail
L2 ::5:5:5:5/128 [20/115] medium priority
  via fe80::14, GigabitEthernet0/0/0/0.543, XRv14, Weight: 0
    FRR backup via fe80::2, GigabitEthernet0/0/0/0.513, CSR2, Weight: 0
    P: No, TM: 30, LC: No, NP: No, D: No, SRLG: Yes
  via fe80::4, GigabitEthernet0/0/0/0.534, CSR4, Weight: 0
    FRR backup via fe80::2, GigabitEthernet0/0/0/0.513, CSR2, Weight: 0
    P: No, TM: 30, LC: No, NP: Yes, D: No, SRLG: Yes
src CSR5.00-00, ::5:5:5:5
```

It would be ideal if we could use CSR1 to backup the path through XRv14 and CSR2 to backup the path through CSR4. This way, we achieve node protection for the primary paths using two node-protecting LFAs for maximal redundancy. We can do this by telling XR to evaluate the node-protect (NP) attribute, which it was not doing by default.

```
! XRv13
router isis 1
 address-family ipv6 unicast
  fast-reroute per-prefix tiebreaker node-protecting index 5
```

We can clearly see that that CSR1 backs up XRv14 and CSR2 backs up CSR4 as desired. After the SRLG attribute is evaluated, node-protection comes next, which allows XRv13 to more intelligent select LFAs. Tuning these tie-breakers must be carefully considered based on the network architecture since adjusting the selection process could have undesirable affects. In this case, we tuned the process to achieve a highly desirable result.

```
RP/0/0/CPU0:XRv13#show isis ipv6 fast-reroute ::5:5:5:5/128 detail

src CSR5.00-00, ::5:5:5:5
```

37.2.2.2 Remote LFA

Remote LFA on XR using LDPv6 is probably beyond the scope of the blueprint given it is supported on XR 5.3.0 whereas the test uses version XR 5.2.0. For completeness, we will examine it briefly; LDPv6 is also introduced in XR 5.3.0 and is not discussed in detail. It works identically to LDP for IPv4 by allocating labels to IPv6 prefixes instead of IPv4 prefixes. OSPFv3 does not support rLFA at this time, so only IS-IS is tested. Basic rLFA concepts like P-space, extended P-space, Q-space, and PQ-node are not discussed again as they are identical between all rLFA variations (OSPF, IS-IS, IPv4, IPv6).

We will use a square topology of XRv routers for this test. The network diagram is below. IS-IS level 2 is enabled everywhere, all transit links have only link-local addressing. The OSPFv3 and LDP RIDs are hardcoded to X.X.X.X where X is the router number. The IPv6 loopbacks are ::X:X:X:X/128 and there is no IPv4 configuration anywhere.

We enable rLFA under each interface within IS-IS on XRv11 so that it can tunnel traffic to XRv14 to protect its connected links to XRv12 and XRv13. The rLFA configuration is staged under all of the other routers, but it needs to be activated with the base command "fast-reroute per-prefix" in XR.

```
! XRv11
router isis 1
interface GigabitEthernet0/0/0/0.512
  address-family ipv6 unicast
    fast-reroute per-prefix
    fast-reroute per-prefix remote-lfa tunnel mpls-ldp
    fast-reroute per-prefix remote-lfa maximum-metric 20

interface GigabitEthernet0/0/0/0.513
  address-family ipv6 unicast
    fast-reroute per-prefix
    fast-reroute per-prefix remote-lfa tunnel mpls-ldp
    fast-reroute per-prefix remote-lfa maximum-metric 20
```

The basic LDPv6 configuration is shown below but is not discussed in detail. The RID is set manually as is the discovery transport-address; IPv4 is not running so the TCP session is IPv6-based as well. I also disable LDPv4 globally since it doesn't need to be enabled. Last, I enabled LDPv6 on the proper interfaces. Similar configurations exist for all other XR routers in the network.

```
! XRv11
mpls ldp
default-vrf implicit-ipv4 disable
router-id 11.11.11.11
address-family ipv6
  discovery targeted-hello accept
  discovery transport-address ::11:11:11:11

interface GigabitEthernet0/0/0/0.512
  address-family ipv6

interface GigabitEthernet0/0/0/0.513
```

```
address-family ipv6
```

The output below shows us that the route to XRv12's loopback is protected via an rLFA tunnel to XRv14. This will show even if LDPv6 is broken (that is, the targeted session fails).

```
RP/0/0/CPU0:XRv11#show isis ipv6 fast-reroute detail ::12:12:12:12/128
L2 ::12:12:12:12/128 [10/115] medium priority
    via fe80::12, GigabitEthernet0/0/0/0.512, XRv12, Weight: 0
        Remote FRR backup via XRv14 [::14:14:14:14], via fe80::13,
GigabitEthernet0/0/0/0.513 XRv13, Weight: 0
    P: No, TM: 20, LC: No, NP: No, D: No, SRLG: Yes
    src XRv12.00-00, ::12:12:12:12
```

Next, we check XRv11 to make sure that it learns the LDP label for ::12:12:12:12/128 from XRv14 (using its RID that looks like an IPv4 address). Checking the neighbor (using the IPv6 address), we see the proper prefix association.

```
RP/0/0/CPU0:XRv11#show mpls ldp ipv6 discovery 14.14.14.14
Local LDP Identifier: 11.11.11.11:0
Discovery Sources:
  Targeted Hellos:
    ::11:11:11:11 -> ::14:14:14:14 (active), xmit/rcv
    LDP Id: 14.14.14.14:0
    Hold time: 90 sec (local:90 sec, peer:90 sec)
```

```
RP/0/0/CPU0:XRv11#show mpls ldp neighbor ::14:14:14:14
Peer LDP Identifier: 14.14.14.14:0
  TCP connection: ::14:14:14:14:60551 - ::11:11:11:11:646
  Graceful Restart: No
  Session Holdtime: 180 sec
  State: Oper; Msgs sent/rcvd: 10/11; Downstream-Unsolicited
  Up time: 00:03:14
  LDP Discovery Sources:
    IPv4: (0)
    IPv6: (1)
    Targeted Hello (::11:11:11:11 -> ::14:14:14:14, active)
  Addresses bound to this peer:
    IPv4: (0)
    IPv6: (1)
    ::14:14:14:14
```

Lastly, we check the LDPv6 LIB to ensure we learn XRv14's label for ::12:12:12:12/128 which is 94011. This is the inner label of the rLFA tunnel; the outer label will be XRv13's label for ::14:14:14:14/128, which is 93002. After IGP convergence, XRv1 will use XRv13's label for ::12:12:12:12/128 directly, which is 93016, and the rLFA tunnel is torn down since there is no more PQ-node. The rLFA label stack would

be {93002 94011} assuming rLFA was in use during the IGP convergence period. This is the same logic we evaluated with rLFA earlier for both OSPFv2 and IPv4 IS-IS.

```
RP/0/0/CPU0:XRv11#show mpls ldp ipv6 bindings ::12:12:12:12/128 neighbor
14.14.14.14:0
::12:12:12:12/128, rev 8
    Local binding: label: 91004
    Remote bindings: (2 peers)
        Peer                Label
        -----
        14.14.14.14:0       94011
```

```
RP/0/0/CPU0:XRv11#show mpls ldp ipv6 bindings ::14:14:14:14/128 neighbor
13.13.13.13:0
::14:14:14:14/128, rev 6
    Local binding: label: 91001
    Remote bindings: (3 peers)
        Peer                Label
        -----
        13.13.13.13:0       93002
```

```
RP/0/0/CPU0:XRv11#show mpls ldp ipv6 bindings ::12:12:12:12/128 neighbor
13.13.13.13:0
::12:12:12:12/128, rev 8
    Local binding: label: 91004
    Remote bindings: (3 peers)
        Peer                Label
        -----
        13.13.13.13:0       93016
```

As a final check, we validate the CEF entry and ensure the label binding is correct. I don't know why the second label is not shown in the label stack for the backup path, but without BFD we can't actually test it. CEF imposes the topmost label and I am assuming the rLFA process, behind the scenes, is imposing label 94011 before CEF sees it.

```
RP/0/0/CPU0:XRv11#show cef ipv6 ::12:12:12:12/128

```

Additional Reading – Reference configurations "rlfa-ipv6"

37.3 Convergence optimizations for BGP

BGP has many special timers that can tune its behavior. This lab explores many of them within the context of IPv4 and IPv6 AFIs. The ordinary “neighbor timers” are evaluated in a specific section dedicated to individual protocol hellos and are not discussed here. The lab topology is similar to that seen in the inter-AS multicast section, except that the BGP IPv4/v6 multicast AFIs have been disabled. Other multicast features remain enabled but are not the focus of this test, and are thus ignored. The diagram is shown again for reference. There are 4 different ASes which have many external and internal BGP peerings for additional testing. Each AS has its own IPv4/v6 IGP for intra-AS reachability. Unlike the inter-AS multicast lab, I enabled BGP IPv4/v6 unicast on CSR1 through CSR4; these were test hosts in the multicast lab but are now used as BGP routers for additional testing. XRV1, CSR10, and CSR8 are route-reflectors for both AFIs in their respective ASes, while AS11 has a full mesh of iBGP peers.

The first timer is the advertisement interval. This timer determines the rate at which advertisements are sent to a peer; the default for eBGP is 30 seconds while iBGP is 0 seconds (no delay). This allows for updates to be grouped together and advertised in chunks rather than independently. This grouping mechanism is loosely analogous to the OSPF LSA-group pacing mechanism for LSA age refreshing. When there are multiple changes in an AS a few seconds apart, they are propagated immediately within the AS but delayed externally so that a more efficient update can be assembled. Since the primary purpose of BGP was very high scalability, this could reduce convergence effectiveness. Before making configuration adjustments, we can confirm the default timers on XE and XR for eBGP and iBGP peers. A timer of 0 seconds, the iBGP default, implies no delay in propagating updates.

```
R6#show bgp ipv4 unicast neighbors | include ^BGP|advertisement
BGP neighbor is 9.0.0.10, remote AS 9, internal link
  Default minimum time between advertisement runs is 0 seconds
BGP neighbor is 10.6.9.9, remote AS 11, external link
  Default minimum time between advertisement runs is 30 seconds
BGP neighbor is 10.6.12.12, remote AS 8, external link
  Default minimum time between advertisement runs is 30 seconds
```

```
RP/0/0/CPU0:XRv4#show bgp ipv4 unicast neighbors | utility egrep
'^BGP|advertisement'
BGP neighbor is 7.0.0.11
  Minimum time between advertisement runs is 0 secs
BGP neighbor is 10.9.14.9
  Minimum time between advertisement runs is 30 secs
  Policy for incoming advertisements is PASS
  Policy for outgoing advertisements is PASS
BGP neighbor is 10.12.14.12
  Minimum time between advertisement runs is 30 secs
  Policy for incoming advertisements is PASS
  Policy for outgoing advertisements is PASS
```

We can confirm this behavior by creating two changes in quick succession within AS 7 and observing the behavior. Adding a new network on CSR2 into IPv4 BGP, this is advertised immediately to iBGP peers, and then to eBGP peers. The iBGP advertisement interval expires immediately so when a second network is added, it is also advertised to iBGP peers immediately. The eBGP advertisement interval begins counting down from 30, and until it expires, updates will not be sent towards a given peer.

To test it, on CSR2 and CSR6 I enable BGP update debugging for IPv4. Adding the first network to CSR2, we see that CSR2 advertises it to its iBGP peers immediately, and when CSR6 receives it from the iBGP RR (CSR10), it advertises it to its eBGP peers immediately. Outbound updates are shown in green with inbound updates shown in yellow. The clocks on CSR2 and CSR6 are not synchronized, but it does not matter since we are only comparing time differences in each local router. The difference for both is 1 ms, which is effectively zero.

! CSR2

```

Quickly adding a second network into IPv4 BGP on CSR2 (within a few seconds), we notice that CSR2 advertises it to its iBGP peers immediately, but CSR6 waits. The first eBGP update was sent at 07:41:19 which means the next update should not be sent before 07:41:49; it might be a few seconds after, but never before. CSR6 receives the update immediately but cannot advertise it until 07:41:49 which is when the advertisement-interval for eBGP peers will expire. The timestamp of the eBGP update for the second network proves this.

```

! CSR2
interface Loopback1

07:41:49.827: BGP(0): (base) 10.6.12.12 send UPDATE (format) 9.2.2.22/32,
next 10.6.12.6, metric 0, path Local

```

The construction of these more efficient updates is handled by the BGP update-group feature. When updates are assembled, they are assembled once and replicated to peers that have the same outbound policies. These outbound policies include route filters, advertisement intervals, etc. Internal and external peers are always in different update groups regardless of the outbound policies. We can see the update groups by specifying a neighbor and then seeing all of the members. In this case, both XRv2 and CSR9 are in the same update group, which is why only one update was created above.

```

R6#show bgp ipv4 unicast update-group 10.6.12.12
BGP version 4 update-group 6, external, Address Family: IPv4 Unicast
  BGP Update version : 275/0, messages 0, active RGs: 1
  Topology: global, highest version: 275, tail marker: 275
  Format state: Current working (OK, last minimum advertisement interval)
                 Refresh blocked (not in list, last not in list)
  Update messages formatted 98, replicated 171, current 0, refresh 0, limit
1000
  Number of NLRI's in the update sent: max 3, min 0
  Minimum time between advertisement runs is 30 seconds
  Has 2 members:
    10.6.12.12 10.6.9.9

```

Adjusting the advertisement-interval for one of the peers will break the update group efficiency. To make things interesting, I will increase the advertisement-interval (slow the convergence) towards CSR9. We now see two update groups, one with each eBGP peer, due to the advertisement interval changing. The output also, assuming the interval is counting down, will show you the time remaining as demonstrated below.

```

! CSR6
router bgp 9
  address-family ipv4
    neighbor 10.6.9.9 advertisement-interval 45

R6#show bgp ipv4 unicast update-group
BGP version 4 update-group 6, external, Address Family: IPv4 Unicast
  BGP Update version : 277/0, messages 0, active RGs: 1
  Topology: global, highest version: 277, tail marker: 277
  Format state: Current blocked (minimum advertisement interval, last minimum
advertisement interval)

```

```

Refresh blocked (not in list, last not in list)
Update messages formatted 100, replicated 175, current 0, refresh 0, limit
1000
Number of NLRI's in the update sent: max 3, min 0
Minimum time between advertisement runs is 30 seconds (expires in 1
seconds)
Has 1 member:
10.6.12.12

BGP version 4 update-group 7, external, Address Family: IPv4 Unicast
BGP Update version : 277/0, messages 0, active RGs: 1
Topology: global, highest version: 277, tail marker: 277
Format state: Current blocked (minimum advertisement interval, last minimum
advertisement interval)
Refresh blocked (not in list, last not in list)
Update messages formatted 11, replicated 11, current 0, refresh 0, limit
1000
Number of NLRI's in the update sent: max 3, min 0
Minimum time between advertisement runs is 45 seconds (expires in 43
seconds)
Has 1 member:
10.6.9.9

```

Quickly retesting the advertisement using the test networks on CSR2, we enable debugging on CSR6 only. Since we didn't change the iBGP settings, we won't confirm how advertisement works over iBGP again. We see that CSR6 receives the update 9.2.2.2/32 at time 08:00:22 and the update for 9.2.2.22/32 at time 08:00:28, about 6 seconds later. 9.2.2.2/32 was immediately advertised to both eBGP peers in two separate updates (thanks to the two separate update-groups) and their advertisement-intervals behind counting down.

```

! CSR6
08:00:22.850: BGP(0): 9.0.0.10 rcvd UPDATE w/ attr: nexthop 9.0.0.2, origin

> 9.0.0.2(global) to main IP table

```

30 seconds after the time the first update is sent to XRv2, the update for 9.2.2.22/32 is also sent; this is time 08:00:52. 45 seconds after that initial time (or 15 seconds after the update was sent to XRv2), the update for 9.2.2.22/32 is sent to CSR9 since we slowed down the advertisement-interval. This later time is 08:01:07. This proves that the advertisement-interval works as expected.

```
! CSR6
08:00:52.733: BGP(0): (base) 10.6.12.12 send UPDATE (format) 9.2.2.22/32,

10.6.9.6, metric 0, path Local
```

The feature works identically in XR, and for variety we will perform our configurations for IPv6 BGP. Currently, XRv2 and CSR9 are in the same update-group for this AFI due to their identical outbound filtering RPLs and matching advertisement-intervals.

```
RP/0/0/CPU0:XRv4#show bgp ipv6 unicast update-group neighbor fd00:10:9:14::9
Update group for IPv6 Unicast, index 0.3:
  Attributes:
    Outbound policy: PASS
    First neighbor AS: 11
    Directly connected IPv6 EBGP
    4-byte AS capable
    Non-labeled address-family capable
    Minimum advertisement interval: 30 secs
  Update group desynchronized: 0
  Sub-groups merged: 8
  Number of refresh subgroups: 0
  Messages formatted: 201, replicated: 292
  All neighbors are assigned to sub-group(s)
  Neighbors in sub-group: 0.1, Filter-Groups num:1
    Neighbors in filter-group: 0.4(RT num: 0)
      fd00:10:9:14::9
      fd00:10:12:14::12
```

Modifying an advertisement interval will break this. In this case, I reduce the interval to 15.5 seconds on the peer to XRv2 (15 seconds plus 500 ms). XR adds greater capability by permitting millisecond granularity as well. However, the configuration is per-neighbor, not per-neighbor per-AFI. Even though we only test IPv6, this adjustment affects all AFIs negotiated to a given neighbor. Checking the update groups, we can see the update group has been split as the advertisement intervals differ (30 vs. 15.5 seconds). For brevity (and because XR's BGP update debugging is not very clear) we will not test this in real-time, but the effect is identical to XE.

```
! XRv4
router bgp 7

fd00:10:12:14::12
```

The next timer is the BGP scan-time. This is the timer that is used for BGP to “walk the RIB” to verify IGP reachability for BGP next-hops. This occurs every 60 seconds by default, and in order to see it in action, we have to disable a smarter feature known as next-hop tracking (NHT), which is discussed later. Since the scan-time is timer-based and can be tuned very coarsely, it is not a good choice for event-driven or high-availability architectures. This is another per-AFI feature; below I show the defaults for IPv4/IPv6 on XE and XR.

```
R10#show bgp ipv4 unicast summary | include scan
BGP activity 93/55 prefixes, 406/352 paths, scan interval 60 secs
```

```
R10#show bgp ipv6 unicast summary | include scan
BGP activity 93/55 prefixes, 406/352 paths, scan interval 60 secs
```

```
RP/0/0/CPU0:XRv1#show bgp ipv4 unicast | include scan
BGP generic scan interval 60 secs
BGP scan interval 60 secs
```

```
RP/0/0/CPU0:XRv1#show bgp ipv6 unicast | include scan
BGP generic scan interval 60 secs
BGP scan interval 60 secs
```

To disable NHT and adjust the scan timer concurrently for brevity, I issue the commands below. The scanner has been set to 3 times its normal speed so that we can detect next-hop changes in 20 seconds. NHT cannot be disabled on XR, but we will increase the next-hop trigger delays to larger numbers than the scan time which effectively disables it. NHT is discussed in greater detail later.

```
! CSR10
router bgp 9
  address-family ipv4
    no bgp nexthop trigger enable
    bgp scan-time 20

! XRv1
router bgp 7
  address-family ipv6 unicast
    bgp scan-time 20
    nexthop trigger-delay critical 30000
    nexthop trigger-delay non-critical 30000
```

Before testing this with any prefixes, we can watch the scanner in action by debugging BGP events. On XE, I enable the debugging for IPv4 unicast yet the debug shows all of the scanners. Notice that all of the scanners start at once, but then the IPv4 run runs twice more 20 seconds apart, while the others are still waiting for their next cycle of 60 seconds.

```
R10#debug bgp ipv4 unicast events
02:54:32.322: BGP: tbl IPv4 Unicast:base Performing BGP Nexthop scanning for general scan
02:54:32.322: BGP(0): Future scanner version: 5972, current scanner version: 5971
02:54:32.322: BGP: tbl IPv6 Unicast:base Performing BGP Nexthop scanning for general scan
02:54:32.322: BGP(1): Future scanner version: 5958, current scanner version: 5957
02:54:32.322: BGP: tbl L2VPN E-VPN:base Performing BGP Nexthop scanning for general scan
02:54:32.322: BGP(10): Future scanner version: 5958, current scanner version: 5957
02:54:32.322: BGP: tbl MVPNV4 Unicast:base Performing BGP Nexthop scanning for general scan
02:54:32.322: BGP(15): Future scanner version: 5958, current scanner version: 5957
02:54:32.322: BGP: tbl MVPNV6 Unicast:base Performing BGP Nexthop scanning for general scan
```

```

02:54:32.322: BGP(16): Future scanner version: 5958, current scanner version: 5957
02:54:52.325: BGP: Regular scanner timer event
02:54:52.325: BGP: tbl IPv4 Unicast:base Performing BGP Nexthop scanning for nhop scan
02:54:52.325: BGP(0): Future scanner version: 5973, current scanner version: 5972
02:55:12.324: BGP: Regular scanner timer event
02:55:12.324: BGP: tbl IPv4 Unicast:base Performing BGP Nexthop scanning for nhop scan
02:55:12.324: BGP(0): Future scanner version: 5974, current scanner version: 5973

```

The output is similar on XR. We can see the scans running 20 seconds apart.

```

RP/0/0/CPU0:XRv1#debug bgp event afi ipv6 unicast

routing table
[snip]
02:58:43.027 : bgp[1052]: [default-event] (ip6u): Scanning IPv6 Unicast
routing table
[snip]

```

To test it, I will reduce the scan timer even further on CSR2 to 10 seconds. This creates a log message warning the user about potential CPU issues as the scanner will scan all prefixes in the BGP table, even non-best-paths. NHT is also disabled on CSR2 which allows the scanner to operate properly. Then, I shut down CSR6's loopback. After about 40 seconds, this will also kill the BGP session to CSR10, but we see the work of the scanner with respect to the next-hop reachability of all eBGP routes learned from next-hop 9.0.0.6. When the loopback gets shut down, IGP converges quickly and for a few seconds, CSR2 still thinks the BGP routes have valid next-hops. After the scanner runs, those next-hops become inaccessible and the BGP routes are no longer candidates for the best-path.

```

! CSR2
R2(config-router-af)#bgp scan-time 10
%BGP-5-AGGRESSIVE_SCAN_TIME: bgp scan-time configuration less than 15 seconds
can cause high cpu usage by BGP Scanner.

```

Before CSR6's loopback is shutdown, the "baseline" network show commands are below. 9.0.0.6/32 is reachable and the BGP prefixes that rely on it are candidates for the best-path selection algorithm.

```

R2#show ip route 9.0.0.6
Routing entry for 9.0.0.6/32
  Known via "ospfv3 9", distance 110, metric 3, type intra area
  Last update from 9.2.5.5 on GigabitEthernet2.525, 00:00:44 ago

```

Routing Descriptor Blocks:

```
* 9.2.5.5, from 9.0.0.6, 00:00:44 ago, via GigabitEthernet2.525
  Route metric is 3, traffic share count is 1
```

```
R2#show bgp ipv4 unicast 8.0.0.3/32
BGP routing table entry for 8.0.0.3/32, version 248
Paths: (1 available, best #1, table default)
  Not advertised to any peer
  Refresh Epoch 2
  8
    9.0.0.6 (metric 3) from 9.0.0.10 (9.0.0.10)
      Origin incomplete, metric 0, localpref 100, valid, internal, best
      Originator: 9.0.0.6, Cluster list: 9.0.0.10
      rx pathid: 0, tx pathid: 0x0
```

IGP has already withdrawn reachability to 9.0.0.6/32 but BGP is not yet aware. This is the purpose of the scanner; it detects these IGP changes and update the information about the BGP next-hop, such as the accessibility, metric, etc.

```
R2#show ip route 9.0.0.6
% Subnet not in table
```

```
R2#show bgp ipv4 unicast 8.0.0.3/32
BGP routing table entry for 8.0.0.3/32, version 248
Paths: (1 available, best #1, table default)
  Not advertised to any peer
  Refresh Epoch 2
  8
    9.0.0.6 (metric 3) from 9.0.0.10 (9.0.0.10)
      Origin incomplete, metric 0, localpref 100, valid, internal, best
      Originator: 9.0.0.6, Cluster list: 9.0.0.10
      rx pathid: 0, tx pathid: 0x0
```

When the scanner runs, it notices that 9.0.0.6 is inaccessible, and marks the BGP prefixes that use this next-hop as such. The debug doesn't show us the exact scanner activity; it only reveals that the scanner ran according to schedule.

```
! CSR2
03:16:13.780: BGP: Regular scanner timer event
03:16:13.780: BGP: tbl IPv4 Unicast:base Performing BGP Nexthop scanning for
nhop scan

Paths: (1 available, no best path)
  Not advertised to any peer
  Refresh Epoch 2
  8
    9.0.0.6 (inaccessible) from 9.0.0.10 (9.0.0.10)
      Origin incomplete, metric 0, localpref 100, valid, internal
      Originator: 9.0.0.6, Cluster list: 9.0.0.10
      rx pathid: 0, tx pathid: 0

```

The BGP scanner is similar to RIP for unicast routing. Being timer-based, it does not work in large deployments where routing changes occur frequently, nor does it facilitate an end-to-end HA design. The NHT feature was introduced as an event-driven mechanism; the BGP “RIB watcher” process maintains a list of all BGP next-hops. This process will report back to BGP when one of two events happen: the next-hop becomes unreachable or the IGP metric to the next-hop changes. The first event is more important and, in most cases, should be reported more quickly; the default is 5 seconds in XE. This value should be tuned to slightly longer than it takes IGP to converge because notifying BGP of a next-hop failure in a timely manner is not valuable unless there is an alternative path. Alerting BGP before IGP has a chance to calculate the backup path means that routes will be marked inaccessible and may be withdrawn entirely. Waiting a second or so is a less disruptive option than immediate withdrawal. The NHT delay value can be set to as low as 0 seconds, which implies no delay, and should only be used in cases where some sort of IP fast-reroute is in play. This may include ECMP, OSPF LFA, ISIS LFA, or even basic EIGRP feasible successor designs. For the demonstration, I configure the feature on CSR9 and XRv2. Notice that only XR allows us to differentiate between “critical” events, such as prefix reachability, and “non-critical” events, such as IGP metric changes. The defaults for these two event types is 0 and 3 seconds, respectively, so XR assumes you have an immediately-converging IGP by default. XR measures these timers in milliseconds while XE measures it in seconds.

```

! CSR9
router bgp 11
  address-family ipv6
    bgp nexthop trigger delay 2

! XRv2
router bgp 8
  address-family ipv4 unicast
    nexthop trigger-delay critical 2000
    nexthop trigger-delay non-critical 4000

```

Before testing this, we can also specify a route-map/RPL to determine which routes can qualify as next-hops. Although not specifically related to the delay adjustments, this is useful for avoiding aggregate routes. For example, we may want to adjust certain iBGP nodes to always prefer prefixes of length 30 or longer for next-hops. This would cover transit links redistributed into IGP or next-hop-self on ASBRs using their loopbacks. It ensures that the route recursion doesn’t select a default route, for example,

then claim the next-hop is reachable. All next-hops would be reachable in this case, which is undesirable. For IPv6, next-hops should be length /64 or longer, which means that the route is likely not an aggregate.

```
! CSR9
ipv6 prefix-list PL_64_AND_LONGER seq 5 permit ::/0 ge 64
route-map RM_BGP_NHOP_V6 permit 10
  match ipv6 address prefix-list PL_64_AND_LONGER

router bgp 11
  address-family ipv6
    bgp nexthop route-map PL_64_AND_LONGER

! XRv2
route-policy RPL_BGP_NHOP
  if destination in (0.0.0.0/0 ge 30) then
    pass
  endif
end-policy

router bgp 8
  address-family ipv4 unicast
    nexthop route-policy RPL_BGP_NHOP
```

Applying this to XRv2, we immediately see a problem. In most real deployments, private transit links would be /30 or longer (or possibly unnumbered, but that is unrelated to this). In this test lab, they are /24. This means that all of the eBGP routes learned on XRv2 will have /24 routes for their next-hops. Below is the BGP table where we can clearly see none of the eBGP routes have best-paths due to next-hop inaccessibility. The iBGP routes, however, are reachable since the next-hop is the advertising iBGP peers loopback address.

```
RP/0/0/CPU0:XRv2#show bgp ipv4 unicast | begin Network
```

```

As an adjustment for this misconfiguration, I add an exception for 10-networks that are exactly /24 in length. This still follows the spirit of the “no aggregates for next-hops” policy since we know the 10.x.x.x/24 routes are not aggregates. The XR RPL structure has an “eq” option so that we don’t have to use “ge 24 le 24” as we would in an XE prefix-list. The BGP routes are immediately valid again since their BGP next-hops are reachable.

```
! XRv2
route-policy RPL_BGP_NHOP
  if destination in (0.0.0.0/0 ge 30) or destination in (10.0.0.0/8 eq 24)
  then
```

```

    pass
endif
end-policy

```

```

RP/0/0/CPU0:XRv2#show bgp ipv4 unicast | begin Network
  Network          Next Hop          Metric LocPrf Weight Path

[snip]

```

We can also view all of the BGP next-hops. XE prints a simple table showing the next-hop addresses and number of BGP prefixes bound to that next-hop which also includes non best-paths. This is specific to the BGP table, not the routing table.

```

R9#show bgp ipv6 unicast nexthops
# Paths Nexthop Address
  14 FD00:10:9:14::14 (FE80::14)
  14 FD00:10:6:9::6 (FE80::6)
   1 200B::4
   2 200B::D

```

The show command in XR is much more involved. It includes many pieces of statistical information which respect to next-hop processing and path changes. It also shows us the configured NHT values for both critical and non-critical events, which serves as a good verification of the configuration. The status codes clearly show which next-hops are reachable, connected versus IGP learned, and other detailed status information. Like CSR9, we see a few connected next-hops for eBGP routes and a few IGP-learned next-hops for iBGP routes.

```

10.12.14.14	[R] [C] [NL]	0	1/0	4d08h (Cri)	16/19

We can drill into a single next-hop as well by specifying the next-hop explicitly. This reveals additional information about the next-hop such as the routing source (RIP), BGP prefix reference counts, and other low-level debugging information.

To test NHT, I will shutdown CSR8's loopback. XRv2 learns this via IGP and it is the next-hop for one prefix, 8.0.0.3/32. This is a RIB failure, but it doesn't matter for the purpose of this test. The slow

convergence of RIP will take up to 180 seconds for this route to be invalidated, and once that happens, the NHT delay is 2 seconds longer. Once the route is withdrawn (debug reveals this), a critical next-hop change occurs. BGP marks the next-hop as inaccessible and removes the BGP prefixes associated with this next-hop. We can see a very large metric, but most importantly, a critical event occurred a few seconds before. This “critical event” was the removal of the route. If we issue the command a few seconds later, the next-hop information for 8.0.0.3/32 is removed entirely.

On CSR9, we will actually test the timers in greater detail. I will trigger a non-critical event by changing the bandwidth on CSR4’s loopback interface. EIGRP will recompute a new metric and BGP NHT will notice this. I enable BGP event debugging (only available under the IPv4 parser tree but affects all AFIs) and IPv6 routing table debugs. When EIGRP adds the new (worse) metric, the BGP “RIB watcher” immediately notifies BGP of the change. The prefix 200B::4/128 is still reachable, so this would be a

“non-critical” next-hop change event, and the penalty information applies only to dampening (not configured). Exactly 2 seconds later (the NHT delay, shown in green), BGP begins walking its prefixes for updates as it would have normally done via the scanner in older versions. In between those 2 seconds, in a real network, IGP should have converged. In summary, this means the BGP RIB watcher process intentionally delays notifying BGP in order to give IGP time to converge after a topology change event. Routes that are not directly affected by the next-hop change are still reassessed, as seen below.

```
! CSR9
debug bgp ipv4 unicast events
debug ipv6 routing

[snip]
```

Another global BGP timer is the update-delay and generally applies only to BGP during initial startup. This timer starts counting when the first BGP peer is formed. When the timer expires, the router will begin the BGP best-path selection process for all routes and be allowed to advertise best-paths to peers. The idea is to operate in “read-only” mode for a short time when BGP starts to collect all prefixes from all peers before running best-path initially, which ultimately determines which routes a BGP speaker advertises to others. The default timer is 120 seconds and this is a global BGP setting, not per-AFI. We will test a faster timer on CSR3. This timer is different from the rest because it represents a maximum time; we will configure timer of 30 seconds so that CSR3 could begin advertising updates in some amount of time less than 30 if all prefixes are received. Note that this feature is only valuable when a BGP speaker has multiple peers; with only one peer, there is never a reason to wait once the routes have been received.

```
! CSR9
router bgp 11
  bgp update-delay 30

R9#debug bgp ipv4 unicast events
BGP events debugging is on
```

```
R9#debug bgp ipv4 unicast update
BGP updates debugging is on for address family: IPv4 Unicast
```

We enable debugging and then “clear bgp ipv4 unicast” to restart the entire process. The peer with CSR4 comes up first at 23:21:54. Because this is an iBGP peer, CSR4 immediately advertises its BGP routes to CSR9. For brevity, I do not show all of the other eBGP peer formations and received updates, but this is the “read-only” phase. CSR9 will receive all of these updates from all peers, and having a reasonable (not zero) update-delay allows BGP time to collect this information.

```
! CSR9
23:21:54.579: BGP(0): 11.0.0.4 was the first peer to be established for IPv4
Unicast
23:21:54.579: BGP: nopeerup-delay post-boot, set to default, 60s
23:21:54.579: %BGP-5-ADJCHANGE: neighbor 11.0.0.4 Up
23:21:54.580: BGP: nbr_topo global 11.0.0.4 IPv4 Unicast:base
(0x7F6994DBB708:1) rcvd Refresh Start-of-RIB
23:21:54.580: BGP: nbr_topo global 11.0.0.4 IPv4 Unicast:base
(0x7F6994DBB708:1) refresh_epoch is 2
23:21:54.580: BGP(0): 11.0.0.4 rcvd UPDATE w/ attr: nexthop 11.0.0.4, origin
?, localpref 100, metric 0
23:21:54.580: BGP(0): 11.0.0.4 rcvd 11.0.0.4/32
23:21:54.580: BGP: nbr_topo global 11.0.0.4 IPv4 Unicast:base
(0x7F6994DBB708:1) rcvd Refresh End-of-RIB
```

As soon as the first peer is established, the local router “needs to delay read-only mode” so the BGP UPDATE process must exit. This message is printed continuously, once per second and once per AFI, until RO mode ends. Mixed in with this reminder are the syslog messages that the other BGP peers have come up, but this is less significant since the update-delay begins counting when the first peer comes up, which explains the debug output above. Those peers were discussed above (neighbor forms, updates received, etc) but not shown.

```
! CSR9
23:21:54.969: BGP: tbl IPv4 Unicast:base Generate update check
23:21:54.969: BGP: tbl IPv4 Unicast:base AF needs to delay RO exit
```

After the update-delay expires, about 30 seconds in this case, the IPv4 unicast AFI becomes read-write and the BGP best-path selection process begins. I omit some of the prefixes for brevity but all BGP prefixes are evaluated for their best-paths at this time. The debug makes it easy for troubleshooting this timer as well.

```
! CSR9
23:22:24.670: BGP(base): waited 30s[update delay] for all peers
23:22:24.670: BGP: tbl IPv4 Unicast:base Computed bestpaths, table version

```

Immediately after best-path runs, neighbor updates can be sent provided the advertisement-interval allows for it.

```

! CSR9
23:22:24.674: BGP(0): 11.0.0.13 NEXT_HOP is set to self for net 7.0.0.1/32,
23:22:24.674: BGP(0): (base) 11.0.0.13 send UPDATE (format) 7.0.0.1/32, next
11.0.0.9, metric 0, path 7

```

Although we do not test it due to lack of revealing XR debugs, we configure the BGP update-delay timer on XRv3 for completeness. Because the update-delay is a maximum timer by default in XR, we can optionally enforce this delay as a minimum timer by using the “always” keyword. This forces the specified delay regardless of whether or not BGP receives all prefixes from all peers in a timely manner.

```

! XRv3
router bgp 11
  bgp update-delay 30 always

```

Another minor BGP timer is the nopeerup-delay, which prevents peer formation after some “hard” event. We can delay BGP peers from forming in during four different disruptive events:

1. **Cold-boot:** When the router first boots up. I assume this occurs when the router was powered-off or was forcefully reset (not “reload” command).
2. **NSF-switchover:** After an NSF switchover only.
3. **Post-boot:** When the system is already booted and all peers go down. This includes the “reload” command.
4. **User-initiated:** When a BGP peer is manually cleared by the administrator.

The default value for all of these fields is zero according to the documentation and 60 seconds according to the debug (I trust the debug). The feature only appears supported on XE platforms. This network is not NSF-capable since that feature doesn’t apply to virtual routers, so we can test the other three timers. I configure all timers on CSR6 since it has a combination of internal and external peers.

```

! CSR6
router bgp 7
  bgp nopeerup-delay cold-boot 240
  bgp nopeerup-delay post-boot 300
  bgp nopeerup-delay nsf-switchover 120
  bgp nopeerup-delay user-initiated 30

```

First, I reload CSR6 and immediately enable BGP debugging as soon as the console is available. This will allow us to see the nopeerup-delay post-boot timer of 300 seconds configured above. Based on this test, we see that “post-boot” relates to administrator-initiated reloads as this is the timer revealed in the debugs. However, this feature does not appear to work. All BGP peers form immediately despite the debug saying that the backoff should be 5 minutes. The first log message was printed at 02:32:30 and the first BGP came up ~38 seconds later, which indicates unexpected behavior. This may be a CSR1000v artificiality operating in a virtual environment.

```
! CSR6
debug bgp ipv4 unicast
debug bgp ipv4 unicast events
```

```
02:32:30.646: %VUDI-6-EVENT: [serial number: 92V72A6SE1F], [vUDI: ], vUDI is
successfully retrieved from license file
```

```
02:33:08.388: BGP: ses global 10.6.12.12 (0x7F2109416840:1) Up
02:33:08.388: BGP: nopeerup-delay post-boot [config:300s/default:60s] set to
300s
02:33:08.388: %BGP-5-ADJCHANGE: neighbor 10.6.12.12 Up
```

The user-initiated timer also does not appear to work. Clearing a peer manually, it comes back up almost immediately despite the 30-second delay configured. Although the configuration guide makes reference to this feature typically being used with NSF, it is not listed as a prerequisite. While this test was not able to demonstrate the feature functioning properly, we can at least verify it was configured properly by checking the debugs that show the newly configured values (as observed above).

```
R6#clear bgp ipv4 unicast 10.6.9.9
02:37:46.231: %BGP-3-NOTIFICATION: sent to neighbor 10.6.9.9 6/4
(Administrative Reset) 0 bytes
02:37:46.231: %BGP-5-ADJCHANGE: neighbor 10.6.9.9 Down User reset
02:37:46.231: %BGP_SESSION-5-ADJCHANGE: neighbor 10.6.9.9 IPv4 Unicast
topology base removed from session User reset
02:37:46.387: %BGP-5-ADJCHANGE: neighbor 10.6.9.9 Up
```

The last BGP feature we will test is the slow-peer feature. A slow-peer is a BGP peer that cannot keep up with the routing updates sent to it. For example, peering a large carrier router with a small branch router, then trying to send it many updates very quickly may not work. Since this slow-peer might be in the same update-group as other peers operating correctly, the sending router would be slowing all updates down for all peers in the update-group. The number of updates to be serviced would queue, and convergence is slowed significantly. There are 3 ways to deal with slow-peers:

1. **Slow-peer detection:** The router simply issues a syslog message to notify the administrator of a dynamically-detected slow-peer but takes no action. The update-groups remain intact as they were before the discovery was made; this is just a warning mechanism.
2. **Slow-peer dynamic protection:** The router detects the slow peer and creates a “slow-peer update-group” for this peer, and any other slow peers with identical outbound attributes. Peers can remain in this slow group indefinitely or temporarily until they stop being slow. This feature relies on the slow-peer detection mechanism as well.
3. **Slow-peer static configuration:** This is slow-peer protection but is statically configured. This option may be the result of using slow-peer detection and manually taking action after an internal network policy review, for example. This is also a mechanism to simply force a BGP peer into a different update-group without having to adjust the advertisement-interval.

We will configure all 3 options on XE only as the feature does not appear to be supported on XR. On CSR6, we will enable slow-peer detection for IPv4 unicast (all peers) except XRv2. For IPv6 unicast, we enable it for the eBGP peer CSR9 only. The detection is enabled per-AFI and has a threshold value associated with it. This measurements how “slow” a “slow-peer” is and is 5 minutes by default; this is the difference between the oldest update in the peer’s update queue versus the current time. If an update was added to a peer’s update queue at 12:00 and it is still in the queue at 12:05, the peer is considered slow. Smaller values imply a more strict definition of “slow-peer”, so I reduce it to the minimum value of 2 minutes. I explicitly disabled slow-peer detection to XRv2 for IPv4 and enable it to CSR9 only for IPv6.

```
! CSR6
router bgp 9
  address-family ipv4
    bgp slow-peer detection threshold 120
    neighbor 10.6.12.12 slow-peer detection disable

  address-family ipv6
    neighbor FD00:10:6:9::9 slow-peer detection threshold 120
```

To verify the configuration, we can check the BGP neighbor details per-peer, per-AFI. For IPv4, we see that slow-peer detection is enabled for both CSR10 and CSR9, but not XRv2. For IPv6, only the peer to CSR9 is running the feature.

```
R6#show bgp ipv4 unicast neighbors | include ^BGP|detection
BGP neighbor is 9.0.0.10, remote AS 9, internal link
  Slow-peer detection is enabled, threshold value is 120
BGP neighbor is 10.6.9.9, remote AS 11, external link
  Slow-peer detection is enabled, threshold value is 120
BGP neighbor is 10.6.12.12, remote AS 8, external link
  Slow-peer detection is disabled
```

```
R6#show bgp ipv6 unicast neighbors | include ^BGP|detection
```

BGP neighbor is 2009::A, remote AS 9, internal link
 Slow-peer detection is disabled
 BGP neighbor is FD00:10:6:9::9, remote AS 11, external link
 Slow-peer detection is enabled, threshold value is 120
 BGP neighbor is FD00:10:6:12::12, remote AS 8, external link
 Slow-peer detection is disabled

As seen earlier, adjusting the advertisement-interval for the eBGP peers caused the router to create a different update group for XRv2 and CSR9. As such, CSR6 has three update groups. We can tell this is the case as each update-group has only one member, so in this case, slow-peer detection isn't very effective. Each update-group has a cache (queue) where BGP updates are stored before being sent to peers. The size of the cache is sized dynamically based on available router memory, number of peers, etc. Although an inefficient use of update-groups, this AFI on CSR6 doesn't need to worry about slow-peers as each peer is already in a separate update-group. As a side note, the group "leader" is the peer with the highest IPv4/v6 address, and when BGP prepares an update for the group, it does so targeting the "leader". In a way, BGP is performing business-as-usual by preparing an update for a single peer, although it is replicated to all others in the update-group.

R6#show bgp ipv4 unicast replication

Index	Members	Leader	MsgFmt	MsgRepl	Csize	Current Version	Next Version
6	1	10.6.12.12	221	296	0/1000	554/0	
14	1	9.0.0.10	75	75	0/1000	554/0	
15	1	10.6.9.9	12	12	0/1000	554/0	

For IPv6, we did not make any adjustments to advertisement-intervals, so the eBGP peers are in the same update-group.

R6#show bgp ipv6 unicast replication

Index	Members	Leader	MsgFmt	MsgRepl	Csize	Current Version	Next Version
9	2	FD00:10:6:12::12	734	1449	0/1000	1782/0	
16	1	2009::A	200	200	0/1000	1782/0	

We will attempt to treat CSR9 as a slow-peer. First, we check CSR6 to see how many prefixes it is advertising to CSR9 and find a total of 15.

R6#show bgp ipv6 unicast neighbors FD00:10:6:9::9 advertised-routes | include Total
 Total number of prefixes 15

Next, we define an MQC policy to drop BGP messages shorter than 120 bytes. This is an approximate value used to differentiate small keepalives (60-80 bytes) from larger BGP updates. This will mean that

the BGP updates will be unacknowledged and CSR6 will keep trying to send them. This filter is temporary as it will break basic BGP operation entirely between CSR6 and CSR9.

```
! CSR9
class-map match-all CMAP_DROP_BGP_UPDATES
  match protocol bgp
  match packet length min 120

policy-map PMAP_FILTER
  class CMAP_DROP_BGP_UPDATES
    police 8000 conform-action drop
  class class-default

interface GigabitEthernet2.569
  service-policy input PMAP_FILTER
```

I will configure CSR6 to perform an outbound route-refresh to CSR9 which will trigger the update process.

```
R6#debug bgp ipv6 unicast FD00:10:6:9::9 updates out
BGP updates debugging is on for neighbor FD00:10:6:9::9 (outbound) for
address family: IPv6 Unicast

! CSR6
BGP(1): (base) FD00:10:6:12::12 send UPDATE (format) 2007::1/128, next
FD00:10:6:12::6, metric 0, path 7
BGP(1): (base) FD00:10:6:12::12 send UPDATE (format) 2007::B/128, next
FD00:10:6:12::6, metric 0, path 7
BGP(1): FD00:10:6:12::12 NEXT_HOP part 1 net 2008:8:3:8::/64, next
FD00:10:6:12::12
BGP(1): (base) FD00:10:6:12::12 send UPDATE (format) 2008:8:3:8::/64, next
FD00:10:6:12::12, metric 0, path 8
BGP(1): (base) FD00:10:6:12::12 send UPDATE (format) 200B::9/128, next
FD00:10:6:12::6, metric 0, path 11
```

We check to ensure CSR9 is dropping these large update packets. Although we cannot be 100% sure these are the BGP updates, we are fairly confident this is the case based on the MQC policy.

```
R9#show policy-map interface gig2.569
GigabitEthernet2.569

Service-policy input: PMAP_FILTER

Class-map: CMAP_DROP_BGP_UPDATES (match-all)

Class-map: class-default (match-any)
  85 packets, 7422 bytes
  5 minute offered rate 0000 bps, drop rate 0000 bps
Match: any

```

We can see the updates piling up in the cache for that update-group. Unfortunately, I am not able to find a way to actually make the slow-peer detection discover a slow-peer despite these efforts. This illustrates an example of how a slow-peer could form, though, and in the interest of time I continue on. CSR9's inability to acknowledge dropped BGP packets is probably less of a "slow-peer" issue and more of a fundamentally broken BGP relationship. With professional-grade test equipment to inject thousands of BGP routes, this would be easier to test.

```
R6#show bgp ipv6 unicast replication
```

Index	Members	Leader	MsgFmt	MsgRepl	Csize	Current Version	Next Version
9	2	FD00:10:6:12::12					
			765	1484	5/1000	1789/0	
16	1	2009::A					
			206	206	0/1000	1789/0	

If a slow-peer were detected, the time at which the last detection takes place is recorded in the neighbor details. This is valuable for historical tracking.

```

R6#show bgp ipv6 unicast neighbors FD00:10:6:9::9 | include detect
Slow-peer detection is enabled, threshold value is 120
Last detected as dynamic slow peer: never

```

Beyond detection, we can configure a router to automatically add a slow-peer to its own update group. Since a single slow-peer effectively slows down updates for the entire group, this is often the best method for dealing with slow-peers (as opposed to shutting them down, etc). On CSR9, we will assume XRv4 is a potential slow-peer for both AFIs. For IPv4, the slow-peer will be dynamically added to its own update-group (along with other slow-peers potentially) only when the slow-peer is detected. This implies that slow-peer detection is also enabled when we configure slow-peer protection. After the peer is no longer considered slow (say, the CPU utilization drops sufficiently so that BGP updates can be processed at normal speeds), it can be moved into the normal update group, which is the essence of dynamic recovery. The "permanent" option disables this recovery and is discussed later.

```

! CSR9
router bgp 11
  address-family ipv4
    neighbor 10.9.14.14 slow-peer split-update-group dynamic

  address-family ipv6
    neighbor FD00:10:9:14::14 slow-peer split-update-group dynamic permanent

```

We can verify that slow-peer protection is configured for the IPv4 peer of XRv4. Detection is implicitly enabled, dynamic protection is explicitly enabled, and the peer is allowed to recover. Like the detection timer, the dynamic recovery timestamp will update when the slow-peer is no longer deemed as such.

```

R9#show bgp ipv4 unicast neighbors 10.9.14.14 | include low.peer
Slow-peer detection is enabled, threshold value is 300
Slow-peer split-update-group dynamic is enabled, and active
Last detected as dynamic slow peer: never
Dynamic slow peer recovered: never

```

The output for the IPv6 peer of XRv4 is almost identical. The difference is that the “permanent” keyword implies this neighbor can never recover from being labeled a slow-peer (short of manually clearing it, reloading the router, etc). Once deemed a slow-peer, the router makes no assumption and has no expectation that the peer will ever speed up.

```

R9#show bgp ipv6 unicast neighbors FD00:10:9:14::14 | include low.peer
Slow-peer detection is enabled, threshold value is 300
Slow-peer split-update-group dynamic permanent is enabled, and active
Last detected as dynamic slow peer: never
Dynamic slow peer recovered: never

```

If a peer has been identified as slow, we can clear this penalty manually using the command below. This is the only way for a slow-peer to gracefully recovery from dynamic protection mode with the “permanent” option also applied.

```

R9#clear bgp ipv6 unicast FD00:10:9:14::14 slow

```

Both the slow-peer detection and slow-peer dynamic protection can be configured per neighbor or per-AFI, and I have demonstrated a number of these options. The final option for dealing with slow-peers is to statically configure them on a per-neighbor basis only. This is fail-safe mechanism for breaking the update-group by excluding specific peers known to be slow. Before the slow-peer feature was introduced, adjusting the advertisement-interval was the only way to guarantee this, which is a valid workaround but less elegant.

```

! CSR9
router bgp 11
  address-family ipv4

```

```
neighbor 10.6.9.6 slow-peer split-update-group static
```

When we verify this, the output changes slightly. Slow-peer detection remains disabled because there is nothing to detect; we statically configure this peer as slow. The static mode of the command is enabled, and we know that the timestamps for detection and recovery time do not apply here.

```
R9#show bgp ipv4 unicast neighbors 10.6.9.6 | include low.peer
```

```
Slow-peer split-update-group static is enabled
```

```
Slow-peer detection is disabled
```

```
Slow-peer split-update-group dynamic is disabled
```

```
Last detected as dynamic slow peer: never
```

```
Dynamic slow peer recovered: never
```

Looking at all of CSR9's update-groups, we now expect to see 3. There is one that is common for all iBGP peers since their advertisement-intervals and outbound policies are identical. There is a second for the IPv4 eBGP peer to XRv4, which has slow-peer detection enabled dynamically, and it is currently in a regular update-group (that is, not currently identified as a slow-peer). Other non-slow eBGP peers, if they existed, would also be in this update-group. The final group is the update-group for slow peers and is identified as a "slow update group". Other slow peers would end up in this group if identified as such; XRv4, if dynamically determined to be slow, is an example. **Note: Since the slow-peer syntax is not supported in XR, you can use the "advertisement-interval" to target a slow peer and achieve the same effect.**

```
R9#show bgp ipv4 unicast update-group

Additional Reading – Reference configurations "bgp-conv-timers"

37.4 Convergence optimizations for IGP's

This lab explores the various OSPF and IS-IS fast convergence techniques, specifically related to SPF calculation and topology advertisement. Most of these are detailed timers; dead neighbor detection timers (hellos) are not covered in this section as there is a dedicated section for that. This lab uses the same topology and basic configurations as the LDP lab, except has all advanced LDP features removed. There are multiple IS-IS levels and multiple OSPF areas, which makes it an ideal topology for this test. Both the IS-IS and OSPFv2/v3 testing uses the same set of configurations which are shown beneath the diagram.

Additional Reading – Reference configurations "fast-conv"

37.4.1 IS-IS

IS-IS has a handful of convergence timers which are used to fine-tune how the internal IS-IS components operate. These components include intra-level SPF, partial recalculations for non-intra-level topology or stub network information (PRC), LSP generation adjustments, and more. We will define each one in detail and test some examples.

spf-interval: This is the time between consecutive SPF runs. This is a throttling mechanism, not a dampening mechanism (nothing is disabled or moved into a hold-down state) which is designed to protect the router from IS-IS hogging the CPU during times of continuous network instability within a level. There are three values that make up this throttling mechanism.

The first timer is the max-hold time, which is the maximum time a router waits between SPF. If 2 or more SPF runs are needed, the SPF backoff timer waits twice as long as the previous run up to the max-hold. The default is 10 seconds and this will make more sense when we examine the other 2 timers.

The second value is the initial wait time, which is the time a node waits before starting the first SPF run. Having this be smaller means the first SPF run happens faster, but waiting a short time allows the router to collect more changed LSPs, which might mean less SPF runs overall. The default is 5500 ms.

The third value is how long the router waits from after the completion of the first SPF run to beginning the second. Multiple SPF runs might be necessary if a router receives more LSP updates after the first changes. The default is 5500 ms.

It is challenging to find the perfect values to optimize convergence as this is entirely network dependent. This is best illustrated with examples below. Inside level-1, we will start the first SPF run after 100 ms, with the second run being 200 ms after the first. The max backoff time will be 2 second. Thus, if multiple SPF runs are needed within level-1, they would run at after 100, 200, 400, 800, 1600, and 2000 ms periods; the wait-timer doubles until the max-hold is reached. For level-1, these aggressive timers might be OK if the topology is stable. If more than 6 SPF runs are required, they would all be spaced at 2000 ms apart.

```
! CSR3
router isis LDP
  spf-interval level-1 2 100 200
```

For level-2, more conservative timers might be more appropriate. Here, we will configure the routers to wait 3 seconds before starting SPF, with the next SPF run being 7 seconds later. The max-hold time is 28 seconds, so the SPF runs will occur at 3, 7, 14, and 28 second intervals.

```
! CSR3
router isis LDP
  spf-interval level-2 28 3000 7000
```

We can quickly test these timers in some capacity. Rather than dig into unnecessary detail on the exact operation of SPF, we will perform cursory checks. If we clear IS-IS on CSR10, we can see that ~3 seconds after the adjacency comes back up, SPF begins. We can reveal this with debugs.

```
R3#debug isis spf-events
IS-IS SPF events debugging is on for IPv4 unicast topology base

! CSR3
00:53:18.260: %CLNS-5-ADJCHANGE: ISIS: Adjacency to R10
(GigabitEthernet2.530) Down, neighbor forgot us
00:53:18.332: %CLNS-5-ADJCHANGE: ISIS: Adjacency to R10
(GigabitEthernet2.530) Up, new adjacency

! About 3 seconds later
00:53:21.311: ISIS-SPF: Compute L2 SPT
00:53:21.311: ISIS-SPF: 4 nodes for level-2
[snip]
```

We will also test the more aggressive level-1 timers. If we clear ISIS on a node that isn't connected to CSR3, we won't see an adjacency flap, so we can also enable a debug to show us LSP changes. More generally, the command shows us any event that triggers SPF, and we see that the first LSP change seen by CSR3 starts the 100 ms timer. After 100 ms (perfect timing in this case), SPF runs for level-1.

```
R3#debug isis spf-triggers
IS-IS SPF triggering events debugging is on for IPv4 unicast topology base

! CSR3
01:04:46.046: ISIS-SPF-TRIG: L1, 0000.0000.0009.00-00 TLV contents changed,
code 22
01:04:46.146: ISIS-SPF: Compute L1 SPT
01:04:46.146: ISIS-SPF: 7 nodes for level-1
[snip]
```

prc-interval: This is the time between consecutive partial recalculation (PRC) runs. The command has identical parameters as the spf-interval and is configured on a per-process only (not per-level). The concepts of max-hold, initial-wait, and backoff-wait are measured the same with the exception of the default timers. The max-hold is 5 seconds, the initial-wait is 2 seconds, and the backoff-wait is 5 seconds. This effectively means that the first PRC waits 2 seconds and every PRC afterwards will be run 5 seconds apart. The significant difference is that this feature relates to how often partial recalculations are run, not full SPF invocations. A partial recalculation is invoked when a leaf (stub) network changes, such as an IP route. Inside level-2, we will make the timer a little more aggressive on CSR10. The initial-wait is reduced to 1500 ms so PRC begins faster. The second PRC, if necessary, runs 2500 ms after the first, with a max-hold of 5000 ms (the default). This means that the first PRC would be at the 1500 ms mark, followed by runs after 2500 and 5000 ms periods as needed.

```
! CSR10
router isis LDP
 prc-interval 5 1500 2500
```

To trigger a partial recalculation, we can enable SPF event and trigger debugging on CSR10 (level-2) and clear CSR8 (level-1). This will change the IP routes inside CSR3, and CSR10 will invoke the PRC process to essentially withdraw reachability to these prefixes. The timing was almost perfect with PRC occurring 1499 ms after receiving the LSP update.

```
! CSR10
01:21:53.712: ISIS-SPF: L2 LSP 1 (0000.0000.0003.00-00) flagged for
recalculation from 7FBCAB81848D

01:21:55.211: ISIS-SPF: spf_result: next_hop_parents:0x7FBC415CF020
root_distance:10, parent_count:1, parent_index:4 db_on_paths:1
01:21:55.211: ISIS-SPF: Calculating routes for L2 LSP 1 (0000.0000.0003.00-
00)
[snip]
```

max-lsp-lifetime: Measured in seconds, this is how long the router will retain LSPs learned from other ISIS routers. The default is 1200 seconds (20 minutes) and this is configured per-process, not per-level. A quick check of the database shows many LSPs each with an LSP holdtime of less than 1200 seconds. When an LSP is refreshed, its holdtime is set to the max-lsp-lifetime, and the number counts down to zero. This hold-time is actually carried in the LSP that a router originates.

```
R3#show isis database
Tag LDP:

XRv2.00-00      0x00000241   0x92D8        854           0/0/0
IS-IS Level-2 Link State Database:
LSPID          LSP Seq Num  LSP Checksum  LSP Holdtime  ATT/P/OL
R1.00-00        0x000001F0   0x8FF4        484           0/0/0
R3.00-00        * 0x00000237   0xC4FC        427           0/0/0
R10.00-00       0x0000020F   0x26AF        354           0/0/0
XRv4.00-00      0x00000208   0xA7D1        963           0/0/0
```

On CSR3, we will configure a very aggressive holdtime, so aggressive that other routers don't generate their LSPs fast enough to keep the network stable. If we check CSR8, we can see that the hold-time for CSR3's LSP is now counting down from 120 seconds.

```
! CSR3
router isis LDP
 max-lsp-lifetime 120
```

```
R8#show isis database R3.00-00
```

```
Tag LDP:
```

```
IS-IS Level-1 LSP R3.00-00
```

LSPID	LSP Seq Num	LSP Checksum	LSP Holdtime	ATT/P/OL
R3.00-00	0x0000024F	0x5B68	70	1/0/0

Notice that after the LSP expires ~70 seconds later, it is refreshed immediately by CSR3. The LSP sequence number increases from 0x24F to 0x250, the next number in sequence, and the LSP has a new checksum.

```
R8#show isis database R3.00-00
```

```
Tag LDP:
```

```
IS-IS Level-1 LSP R3.00-00
```

LSPID	LSP Seq Num	LSP Checksum	LSP Holdtime	ATT/P/OL
R3.00-00	0x00000250	0x5969	102	1/0/0

We can confirm this using debug on CSR8. Letting it run a few minutes, we can see the LSP updates coming every 60-90 seconds for all of CSR3's LSPs, to include the DIS. I assume there is some LSP refresh timer approximation happening on CSR3 implicitly as a result of changing the max lifetime. I use yellow and green to show the router and DIS LSPs, respectively.

```
R8#debug isis update-packets
```

```
IS-IS Update related packet debugging is on for router process LDP

```

lsp-refresh-interval: Measured in seconds, this is how long the router will wait before re-flooding its own generated LSPs (local networks, DIS, etc). The default is 15 minutes and this is set per-process, not per-level. This number has to be less than the max-lsp-lifetime since an LSP must be refreshed before

being purged. On CSR3, we will configure this to be 15 seconds, which will generate even more frequent debugging output on CSR8. Now we can see the timers are about 15 seconds apart (slightly faster).

```

```

lsp-gen-interval: This specifies how much time is in between creating new versions of a single LSP. This can be set on a per-process (both levels) or per-level basis. Just like the SPF and PRC calculations, this command has the max-hold, initial-wait, and backoff-wait timers. The max-wait is 5 seconds, the initial-wait is 50 ms (fast), and the backoff-wait is 5 seconds. Essentially this means that the first LSP change is propagated quickly but any subsequent changes occur 5 seconds later. Testing this is a little tricky, but we can easily verify the max-wait and backoff-wait timers. On CSR3, we will slow things down by making the routing wait a full second before propagating any updates, then backing off subsequent updates at 10 seconds each time.

```
! CSR3
router isis LDP
  lsp-gen-interval level-2 10 1000 10000
```

To simulate this, we will add a new loopback to IS-IS on CSR3, then remove it about 2 seconds later. By making the first change, the IS-IS process waits 1 second then floods the update. We can't effectively measure this other than a good guess by watching debug output on other routers. If we wait more than 1 seconds but less than 10 seconds and remove the loopback, this change will not be regenerated until 10 seconds after the first one was.

```
! CSR3
interface Loopback33
  ip address 33.33.33.33 255.255.255.255

router isis LDP
  passive-interface Loopback33
  ! wait 2 seconds
  no passive-interface Loopback33
```

By debugging on CSR1, we can see the first update where there was a “leaf route changed” in topology ID (TID) 0 which is IPv4. This carries the new IPv4 prefix 33.33.33.33/32 which we added to IS-IS. Just under 10 seconds later (9999 ms), another update occurs to say the leaf routes changed again, which indicates the removal of the loopback. Whether we removed the loopback at the 1.1 or 9.9 second mark, the LSP generation throttle would ensure that the time delta here is always 10 seconds given our configuration. We can see the sequence number increments from 0x26A to 0x26B, indicating that the LSP has been updated.

```
! CSR1

```

Another interesting IS-IS feature is incremental SPF (iSPF). This command is used for intra-level SPF calculations to only rebuild the parts of the tree requiring it. In a sparsely-connected graph, this can be very valuable, since a full SPF run is CPU intensive and iSPF can reduce the impact. This is different than PRC which is for prefix information (or any NLRI carried by IS-IS) and is for stub networks. iSPF helps converge a network more efficiently when intra-level links and nodes change state. The feature is interoperable with routers that don’t support it also, so we will enable it on CSR10 only. It can be enabled for level-1, level-2, or both. The numerical argument is somewhat benign; it simply details how long the router should wait before activating IS-IS from the time you configure it. The default is 120 seconds, but I set it to 1 second. If I enter the command, I don’t want the router to wait 2 minutes to obey the instruction.

```
! CSR10
router isis LDP
 ispf level-2 1
```

To test it, I will shutdown the link to XRv4 on CSR1. Since CSR1 is a stubby node, CSR10 should only need to recompute that part of the network without needing to perform much work on CSR3. We don’t examine the whole process in detail, but we can see the iSPF is enabled and functional.

```
R10#debug isis spf-events terse
```

IS-IS SPF events debugging terse is on for IPv4 unicast topology base

```
! CSR10

From 7FBCAB7EBE28
[snip]
```

Another feature is IS-IS fast flood. This is used to ensure that an LSP that causes a reconvergence event (say, a failed node) is flooded to other neighbors before the local router runs SPF. The idea is to quickly “spread the alarm” within the level so other routers can run SPF in parallel, rather than running SPF immediately upon receipt and flooding the LSP later. However, flooding too many LSPs can be counterproductive, so the number can be set between 1 and 15 LSPs, where the default is 5. This often times improves IS-IS convergence in a network, and is configured on CSR3. CSR3 will fast-flood 2 LSPs before running SPF during a reconvergence event.

```
! CSR3
router isis LDP
fast-flood 2
```

These IS-IS timers work identically on IOS-XR. There does not seem to be a PRC interval timer, but the others exist. XR does a better job of labeling the values with their names rather than arraying them in a command with vague context-sensitive help information. LSP-related command are not AFI-specific and are configured under the process. AFI-specific commands are configured under the AFI stanzas.

```
! XRv4
router isis LDP
lsp-gen-interval maximum-wait 4800 initial-wait 600 secondary-wait 1200
level 2
max-lsp-lifetime 1800 level 2
address-family ipv4 unicast
ispf level 2
spf-interval maximum-wait 3000 initial-wait 50 secondary-wait 3000 level 2
```

37.4.2 OSPFv2 and OSPFv3

The mechanism by which OSPF builds a graph, at least within an OSPF area, is very similar to IS-IS within a level. The SPF timers are similar in behavior but vary slightly in syntax. It also introduces many more complicated timers compared to IS-IS as well.

timers throttle spf: This timer is identical to the IS-IS spf-interval timer. The difference is that the timers are arrayed differently on the CLI. First is the initial-wait, then the backoff-wait, then the max-hold. The defaults for each one are 5 seconds, 10 seconds, and 10 seconds, respectively. This means that OSPF waits 5 seconds for the first SPF run (very slow), and 10 seconds for every other run. We will speed things up a bit. In this case, we configure CSR7 to wait 500 ms from the moment it receives an LSA1 or LSA2 update to the time it starts SPF. The second SPF run happens 1500 ms after the first, with subsequent runs happening at the 3000, 6000, and 12000 ms marks. OSPF also shows you this information in a show command, which IS-IS does not.

```
! CSR7
router ospf 92
  timers throttle spf 500 1500 12000
```

```
R7#show ip ospf | include SPF
```

```
Initial SPF schedule delay 500 msec
Minimum hold time between two consecutive SPF 1500 msec
Maximum wait time between two consecutive SPF 12000 msec
[snip]
```

We can verify this with debugging. On CSR4, we will flap a link to create an SPF event (not shown). CSR7 receives the update from XRv2 and CSR4, and the SPF initial timer starts upon receipt of the first SPF-triggering LSA update. Exactly 500 ms later, SPF begins, which is 10 times faster than the default. The 500 ms was a good buffer because it gave CSR7 time to collect another LSA update from CSR4 before running SPF for the first time; a value of 10 ms, for example, would have necessitated at least two SPF runs, since the second LSU from CSR4 would have come in too late to be considered in the first SPF run.

```
R7#debug ip ospf spf intra
OSPF SPF intra debugging is on
```

```
! CSR7
08:26:29.656: OSPF-92 SPF : Detect change in LSA type 1, LSID 92.0.0.12 from
92.0.0.12 area 0
08:26:30.052: OSPF-92 SPF : Detect change in LSA type 1, LSID 92.0.0.4 from
92.0.0.4 area 0
08:26:30.156: OSPF-92 MON : Begin SPF at 477043.804ms, process time 8623ms
[snip]
```

timers throttle lsa: This is equivalent to the IS-IS lsp-gen-interval and uses the same trio of timers we have seen many times. The initial-timer is 0 ms (happens right away), with the backoff and max-hold timers are set to 5 seconds. This means if two interfaces flap on a router in quick succession, one of them is reflected immediately, but the other must wait 5 seconds. By increasing the initial timer to 50 ms or so, you can actually speed up convergence in the network since both link-state changes would be captured in the first update.

```
! CSR7
```

```
router ospf 92
  timers throttle lsa 50 100 500
```

Once we configure these timers, we can confirm them using show commands.

```
R7#show ip ospf | include LSA throttle
  Initial LSA throttle delay 50 msec
  Minimum hold time for LSA throttle 100 msec
  Maximum wait time for LSA throttle 500 msec
```

As a quick test, we will shut down one of CSR7's transit links while showing the clock just before we do (copy/paste works well). First, we enable LSA-generation debugs, then quickly capture a timestamp and shutdown the interface. Since CSR7 is an ABR and its only link to area 1 was lost, we see CSR7 generate LSAs for both areas. The only reason it does this in area 0 is to clear the ABR flag, not because an area 0 link failed. In any case, we can see that these LSAs are rate-limited from being created right away. Exactly 50 ms later, they are generated and flooded soon thereafter.

```
R7#debug ip ospf lsa-generation
OSPF LSA generation debugging is on
```

```
R7(config)#interface gig2.571
R7(config-subif)#do show clock

seq 0x800000CB
```

timers lsa arrival: This timer is measured in ms and serves to ensure a router does not keep accepting the same LSA too quickly. Used in conjunction with the LSA throttle timers earlier for LSA generation, this timer enforces LSA reception instead. The default is 1000 ms and if the same LSA arrives faster than this period, the LSA is dropped. This might mean the LSAs would need to be re-flooded, but it would allow the local router to have a more stable LSDB if one router is generating LSAs too quickly.

```
! CSR7
router ospf 92
  timers lsa arrival 500
```

We can quickly verify this by checking the OSPF summary.

```
R7#show ip ospf | include arrival
  Minimum LSA arrival 500 msec
```

timers pacing flood: This timer determines how long to wait before flooding an LSA on an interface after the last one was sent. When multiple updates need to be sent, they are queued in an interface flood-list. The inter-update interval is controlled with this command. Every interface has a flood-list, and it's hard to actually see the queue grow since the timer is very fast.

```
R7#show ip ospf flood-list GigabitEthernet2.567

      OSPF Router with ID (92.0.0.7) (Process ID 92)

Interface GigabitEthernet2.567, Queue length 0
```

The timer is measured in ms with a default value of 33 ms. We will increase the value to 75 to create more delay between updates to potentially reduce CPU utilization at the cost of slower convergence. We can confirm it by checking the OSPF process summary.

```
! CSR7
router ospf 92
  timers pacing flood 75

R7#show ip ospf | include flood_pacing
  Interface flood pacing timer 75 msec
```

timers pacing retransmission: This timer determines how frequently to retransmit unacknowledged LSAs on a link using the logic described above. The “flood” timer controls the inter-packet flood delay when packets are first flooded, while the “retransmission” timer controls the subsequent inter-packet flood delay which, in a perfect world, would not occur. It makes sense to make the retransmission timer slower than the flood timer to conserve router resources, and by default it is 66 ms (twice the flood timer). The LSAs candidate for retransmission are placed in an interface-level retransmission-list, much

like the flood-list above. The flood/retransmission timers accomplish the same thing but apply to different queues. The configuration and verification is below.

```
! CSR7
router ospf 92
  timers pacing retransmission 150

R7#show ip ospf | include Retrans
  Retransmission pacing timer 150 msec
```

Like the flood-list, each interface keeps track of the LSAs requiring retransmission as well. While the queue is empty, the command to see those LSAs is below.

```
R7#show ip ospf retransmission-list GigabitEthernet2.567

      OSPF Router with ID (92.0.0.7) (Process ID 92)

Neighbor 92.0.0.6, interface GigabitEthernet2.567 address 92.6.7.6
```

timers pacing lsa-group: This timer is meant to optimize the refresh process for aging LSAs. Rather than refresh all LSAs at the 30 minute mark regardless of age, this timer groups LSAs together with similar ages. The default is 240 seconds (4 minutes), which means that LSAs within 4 minutes of one another are refreshed together. This is sometimes referred to as “controlled bursting” and is a better approach than refreshing all LSAs at the 30 minute mark (half of MAXAGE) or refreshing them individually. The smaller the number, the more frequent (but less inclusive) the bursts. We can effectively disable the feature by setting the timer to its maximum value of 1800 (30 minutes). We could also approximate the “individual LSA” refresh approach by using the minimum of 10 seconds. I use a value of 2 minutes, which means there will be twice as many refreshes per 30 minute interval, but each refresh will contain approximately half as many LSAs. Testing these pacing timers is difficult to do in a timely manner, so we will limit verification to some show commands.

```
! CSR7
router ospf 92
  timers pacing lsa-group 120

R7#show ip ospf | include LSA_group
  LSA group pacing timer 120 secs
```

We can do a little extra verification for the LSA-group timer since there is a special command for it. We can see that the grouped updates are approximately 120 seconds apart, and the interval is displayed for sanity. This helps us verify that the configuration is correct. We can also see that the next update is due in about 65 seconds; this number is always less than the LSA-group interval.

```
R7#show ip ospf timers lsa-group
```

OSPF Router with ID (92.0.0.7) (Process ID 92)

Index 7 Timestamp 551212
```

Failure Head 0, Last 0 LSA group failure logged

queue-depth: These commands are not well documented as the IOS XE 3S documentation makes no mention of them. They are self-explanatory though; you can control how many OSPF hellos/updates may exist in the software queue for processing. This will ensure the router doesn't get stuck processing OSPF packets for forever, but also allows to router to have some backlog mechanism. Below, I allow up to 64 hello packets to be queued, but an unlimited number of LSUs. There does not appear to be a show command to verify this.

```
! CSR7
router ospf 92
  queue-depth update unlimited
  queue-depth hello 64
```

ispf: When enabled, SPF will only recalculate the part of the tree that requires it. This works identically in logic to the IS-IS feature seen earlier. We can verify it by looking at the OSPF summary.

```
! CSR7
router ospf 92
  ispf
```

```
R7#show ip ospf | include Increment
Incremental-SPF enabled
```

We can quickly test this by changing the IGP cost on CSR4's loopback (not shown). A minor change like this would cause an IS-IS PRC without needing iSPF enabled, but for OSPFv2, this is an intra-area change to the LSA1, which normally is a full SPF update. With iSPF, this alleviates the need for CSR7 to recompute paths to CSR6, XRv2 or XRv1. OSPF invokes an "Increment" SPF mechanism which, based on the minor change from CSR4's LSA1, can be significantly more CPU-efficient than a full SPF run.

```
! CSR7
OSPF-92 SPF: Detect change in LSA type 1, LSID 92.0.0.4 from 92.0.0.4 area 0
```

```

OSPF-92 INTRA: Initializing to run spf
OSPF-92 INTRA: Running incremental SPF for area 0
[snip]

```

The last OSPFv2 convergence topic is knowing how to read the SPF statistics page, which can be cryptic since the command provides no legend. On CSR7, we can see several SPF runs over the past 24 hours. Below are the key field definitions.

Delta T: Time that has passed from when a given SPF run started to the current time. In the example below, this was about 20 hours ago. Essentially, it says “I started an SPF run this long ago”.

Intra: Time in ms for SPF to process intra-area LSAs, such as LSA1 and LSA2, and to build the topology graph within an area. The timer also accounts for installing intra-area routes in the RIB, which can be a lengthy process. If a topology is densely connected and/or has many IP prefixes, this number can be large.

D-Intra: Same concept as “Intra” except measures the time required to delete intra-area routes (O) from the RIB, measured in ms.

Summ: Same concept as “Intra” except measures the time required to run partial SPF on inter-area LSAs (LSA3) and install them in the RIB. This is also measured in ms.

D-Summ: Same concept as “Summ” except measures the time required to delete inter-area routes (O IA) from the RIB, measured in ms.

Ext: Same concept as “Intra” and “Summ” except measures the time required to run partial SPF on external LSAs (LSA5 and LSA7) and install them in the RIB. This is also measured in ms.

D-Ext: Same concept as “Ext” except measures the time required to delete external (E and N) routes from the RIB, measured in ms.

Total: The sum of all aforementioned counters, measured in ms. This is how long it took the entire SPF process to do everything required, to include additions and deletes for all OSPF route types.

Reason: This is a code that justifies the need to run SPF.

R: A change in a router LSA (type 1) has occurred. This means full SPF (or possibly iSPF) must run within the area since the topology changed or an intra-area prefix changed.

N: A change in a network LSA (type 2) has occurred. This might indicate that a DR failed (which would also be an “R” condition) when the BDR succeeded it, or that a network type was changed to include or exclude the DR election. When the reason is “N”, the reason is often “R” as well.

SA: A change in a summary ASBR LSA (type 4) has occurred. This would change if a new ASBR was detected in an area and the ABRs needed to notify the other areas about it. The opposite is also true; if an ASBR stops performing redistribution, that would trigger a removal of this LSA. Changes in the cost to reach the ASBR would also cause SPF to run using this code.

SN: A change in a summary LSA (type 3) has occurred. If an ABR changes what prefixes it advertises between areas, that would cause a partial SPF run for those prefixes. Changes in the inter-area prefix costs would also trigger SPF using this code.

X: A change in an external LSA (type 5 or 7) has occurred. If an ASBR changes what prefixes it advertises into OSPF via redistribution (or potentially a default route that is not inter-area), that would cause a partial SPF run. Changes in the external prefix costs would also trigger SPF using this code.

Before continuing to OSPFv3, we will configure all of these OSPFv2 timers on XRv1 for completeness. Some timers, such as the retransmission timer, do not appear to exist. The retransmission pacing interval appears to be set to twice the pacing flood interval, which is logical behavior. Incremental SPF does not appear to be supported, either.

```

XR also shows the OSPF statistics for SPF, as well as many other features (TE, interface, and other details). XR also gives you a summary of the reason codes which is very handy. If you forget the XE codes, you can use this command on XR since the codes are identical across platforms.

```
RP/0/0/CPU0:XRv1#show ospf statistics spf
SPF statistics for OSPF 92
```

```
Reason Codes: R - Router-LSA, N - Network-LSA,
              SN - Summary-LSA (IP network),
              SA - Summary-LSA (ASBR), X - AS-external-LSA
```

```

OSPFv3 is very similar to OSPFv2 in terms of how SPF is performed and the timers that are available. Because the original LDP lab did not have OSPFv3 configured, we will configure it quickly on all OSPFv2 routers using the same area boundaries. The configuration is not shown, but we can quickly verify that the loopbacks are all advertised into OSPFv3. Checking the intra and inter-area prefixes, we can see CSR5 and XRv3 are inter-area, while all other loopbacks are in area 0 from XRv2's perspective. CSR6 also originates a default route if the IS-IS IPv6 default route is present, which is an external route.

```

```

The convergence timers and queue-depth adjustments in OSPFv3 work identically to those in OSPFv2, so they are not evaluated again. We can literally copy/paste the OSPFv2 configuration on CSR7 into OSPFv3 and it works the same. We verify it with a similar show command. The only convergence feature not also supported in OSPFv3 is incremental SPF.

```
! CSR7

```

However, one significant improvement introduced by OSPFv3 is the introduction of the intra-area prefix LSA (type 9). OSPFv3 intelligently decouples the topology information from the IP prefix information into two separate LSAs. Legitimate topology changes, such as failed intra-area links or nodes, will trigger an SPF run (LSA1). Minor changes to prefixes within that area, like IS-IS, should not (LSA9). The OSPFv3 SPF statistics table is very similar to the OSPFv2 table with some new entries. Only the new entries are defined below for brevity.

SPT: Since IP prefixes are decoupled from the tree construction process, this is a new field that represents the time it takes to process all LSA1s and to find shortest paths to each node. This does not include interaction with stub networks (IPv4/v6 prefixes), measured in ms.

Prefix: This is the time it takes to process all stub networks (IPv4/v6 prefixes) and installs them in the RIB, measured in ms. In other words, this processes the LSA9s.

We also see new reason codes of “P” and “L”. The “P” code is for “prefix” and represents a partial SPF recalculation when only LSA9 (prefix) information is changed. The “L” code is for “link” and represents changes to the LSA8 Link LSA, which is not discussed here.

```

Changing the IGP cost on a stub network, or perhaps adding/deleting the network entirely, registers only as a “P” to indicate a prefix-based recalculation, which is lightweight. In this example, I add a new loopback to CSR6 while debugging on CSR7. This is one of the most significant improvements of OSPFv3 over OSPFv2.

```
R7#debug ospfv3 spf intra
OSPFv3 SPF intra debugging is on for process 92, IPv6, Default vrf
```

```
! CSR6
interface Loopback66
  ipv6 address ::92:0:0:66/128

OSPFv3-92-IPv6 INTRA: Running SPF for area 0, cause P
OSPFv3-92-IPv6 INTRA: Starting Intra-Area SPF (Prefix)
OSPFv3-92-IPv6 INTRA: Process Prefix LSAs
```

```
R7#show ospfv3 92 statistic
[snip]
00:05:14  0      0      0      0      0      0      0      0      0      R  N  SN  SA  X  L  P
00:05:13  0      0      0      0      0      0      0      0      0      R  N  SN  X  L  P
00:05:10  0      0      0      0      0      0      0      0      0      R  SN  X  L
00:05:04  0      0      0      0      0      0      0      0      0      R  SN  X  P
00:00:42  0      0      0      0      0      0      0      0      0      P
```

This is also true for external routes. Since CSR6 is originating an IPv6 default only when it learns one from IS-IS, we can shut down CSR3’s link to the level-1 domain (not shown). This ultimately causes CSR6 to withdraw the external LSA from area 0; with debugging on CSR7, we can see this SPF get scheduled as well.

```
! CSR7
OSPFv3-92-IPv6 SPF   : Schedule partial SPF for LSA 4005/0/92.0.0.6
```

```
R7#show ospfv3 92 statistic
[snip]
00:15:53  0      0      0      0      0      0      0      0      0      R  SN  X  P
00:11:32  0      0      0      0      0      0      0      0      0      P
```

Unfortunately, the SPF statistic table doesn’t show this as reason “X”. In fact, it doesn’t show any new activity at all, although we know it happened. Even when we bring the link on CSR3 back up (not shown), SPF runs again, but the statistics don’t show it. Personally, I find this SPF statistics command to be of

limited value because there are other cases where it records SPF runs only selectively. I assume this is a cosmetic decision because the fundamental IPv6 OSPFv3 routing is fully functional.

```
! CSR7
```

```
OSPFv3-92-IPv6 SPF : Schedule partial SPF for LSA 4005/1/92.0.0.6
```

```
R7#show ospfv3 92 statistic
```

```
[snip]
```

```
00:16:27 0 0 0 0 0 0 0 0 R SN X P
00:12:05 0 0 0 0 0 0 0 0 P
```

XR has similar output, and since this intra-area prefix calculation is an OSPFv3 feature (not a Cisco-specific enhancement), XR also shows “PFX” as a reason to run partial SPF inside an area. In this example, the SPF run was actually a full run since we see the “R” and “N” codes also, but I illustrate that XR uses “PFX” and not “P” to indicate a prefix-based SPF run. “ASE” stands for AS external, which is equivalent to “X” on XE.

```
RP/0/0/CPU0:XRv1#show ospfv3 92 statistics spf

Regarding OSPFv3 timers on XR, they are very similar to the OSPFv2 timers on XR. Some of them aren’t supported (LSA refresh, etc) but the syntax is otherwise similar, if not identical. They have the same effect as the OSPFv2 timers and are not tested in detail.

```
! XRv1

```

38. Describe, implement, and troubleshoot multi-VRF CE and advanced VRF techniques

This entire section uses a large topology with an MPLS core and several customer VRFs. Every combination of XE and XR serving in PE and CE roles is represented. VRF-Lite for all protocols is tested on

both XE and XR (where supported). Backdoor links for OSPF, EIGRP, and BGP are also examined, along with many other VRF features. The network diagram is below. CSR10 and CSR1 are meant to be generalized “central services” sites so their RTs can be imported/exported as needed for testing. CSR2 and CSR9 are used for traffic leaking and are not part of the MPLS-specific testing. Note that this section is very configuration intensive with the vast majority of it being highly repetitive. Not all configurations will be shown “in line” with the documentation as a result.

Additional Reading - Reference configurations "vrf"

38.1 Multi-VRF CE (VRF-Lite)

This section merges all of the PE-CE routing protocols together with VRF-lite on the CEs. The PE-CE routing techniques are the generally same whether the CE uses VRF-lite or not, but for brevity they are combined here with a single analysis.

38.1.1 Basic VRF-Lite

VRF-Lite is not a difficult feature. Just like a VLAN represents a virtual switch, a VRF represents a virtual router. Unless manually configured, traffic/routes do not leak between VRFs, which provides good software isolation between tables. This is especially useful for modeling larger networks from a single router. VRFs were initially designed for MPLS L3VPN PE routers so that customer routes could be kept isolated from other customers; for L3VPN, the main motivation was overlapping address space within different customer networks. VRF-Lite removes the MPLS overtone and simply segments a router into SVRs, as discussed earlier. The concept of RD is only relevant when the VRF needs to participate in any kind of BGP routing. XR correctly places the RD configuration under BGP because it only has relevance to BGP. In XE, we don't need to define an RD under the VRF unless BGP is used. RTs serve no purpose for

VRF-Lite (assuming no route leaking) and can be skipped for now. Notice that the non-BGP related VRFs don't have RDs configured. We still have to initialize each AFI we want the VRF to support; this causes the router to allocate the appropriate RIB/FIB constructs for the specified AFIs.

```
! Basic XE VRF-Lite
vrf definition BGP
  rd 214:104
  address-family ipv4
  address-family ipv6

vrf definition EIGRP
  address-family ipv4
  address-family ipv6

! Basic XR VRF-Lite
vrf BGP
  address-family ipv4 unicast
  address-family ipv6 unicast

vrf RIP
  address-family ipv4 unicast
  address-family ipv6 unicast

router bgp 104
  vrf BGP
    rd 214:104
```

Verifying the configuration is very straightforward. Since there are no advanced VRF features activated (yet), we can use the XE summary commands to verify the VRFs. The only real difference between any pair of VRFs might be the presence or absence of an RD. We can also see the AFIs and interfaces.

```
R5#show vrf ISIS
  Name          Default RD    Protocols    Interfaces
  ISIS          <not set>    ipv4,ipv6    Gi2.103
                                     Lo103

R5#show vrf BGP
  Name          Default RD    Protocols    Interfaces
  BGP           214:104     ipv4,ipv6    Gi2.104
                                     Lo104
                                     Gi2.204
```

In XR, the interfaces are not shown in summary form, but are revealed in the VRF details. We can verify the RD, interface, and AFIs. Not seeing IPv6 enabled under the first VRF, for example, would be a good troubleshooting reason why something like OSPFv3 was not working.

```
RP/0/0/CPU0:XRv3#show vrf OSPF detail | exclude No
VRF OSPF; RD not set; VPN ID not set
```

```
VRF mode: Regular
Description not set
Interfaces:
  GigabitEthernet0/0/0/0.101
  Loopback101
  GigabitEthernet0/0/0/0.201
Address family IPV4 Unicast
Address family IPV6 Unicast
```

```
RP/0/0/CPU0:XRv3#show vrf BGP detail | exclude No
VRF BGP; RD 214:104; VPN ID not set
VRF mode: Regular
Description not set
Interfaces:
  GigabitEthernet0/0/0/0.104
  Loopback104
  GigabitEthernet0/0/0/0.204
Address family IPV4 Unicast
Address family IPV6 Unicast
```

The show command syntax in both platforms changes when introducing VRFs. In XR, the syntax is very deterministic, generally in the format of “show (process) [vrf (vrf-name)] [afi] (feature)” where the VRF and AFI fields are optional. Below are some examples.

```
RP/0/0/CPU0:XRv3#show ipv4 vrf BGP interface brief loopback104
```

Interface	IP-Address	Status	Protocol
Loopback104	192.104.13.13	Up	Up

```
RP/0/0/CPU0:XRv3#show eigrp vrf EIGRP ipv6 neighbors gig0/0/0/0.102
```

IPv6-EIGRP VR(VPN) Neighbors for AS(102) VRF EIGRP							
H	Address	Interface	Hold Uptime (sec)	SRTT (ms)	RTO	Q Cnt	Seq Num
0	Link Local Address: fe80::11	Gi0/0/0/0.102	14 12:43:50	16	200	0	27

```
RP/0/0/CPU0:XRv3#show ospf vrf OSPF our-address
```

Local Address Database for ospf 101, VRF OSPF with ID 0.0.101.13	
192.5.101.13	GigabitEthernet0/0/0/0.201
192.11.101.13	GigabitEthernet0/0/0/0.101
192.101.13.13	Loopback101

The XE syntax also includes the “vrf” keyword for many show commands, but is less deterministic/consistent. For example, the OSPFv2 show commands never reference a VRF, just the process ID, which might be mapped to a VRF. The EIGRP show commands reference the VRF after the AFI, which is backwards compared to XR. The RIP command contains the process and feature before specifying the VRF, which is also inconsistent with the XE EIGRP and all XR commands. In short, the XE commands are inconsistent, which is one of the reasons XR was designed to be simple.

```
R5#show ip ospf 101 interface brief
```

Interface	PID	Area	IP Address/Mask	Cost	State	Nbrs	F/C
Lo101	101	0	192.101.5.5/32	1	LOOP	0/0

0	192.12.102.12	Gi2.102	10	13:31:27	15	100	0	19

```
R5#show ip rip database vrf RIP 192.106.14.14 255.255.255.255
```

```
192.106.14.14/32
```

```
[2] via 192.12.106.12, 00:00:12, GigabitEthernet2.106
```

Interfaces are assigned to VRFs by putting the VRF under that interface. The XR VRF interface syntax is identical to the VRF definition and BGP VRF configuration; it is very consistent. XE uses different commands for each one. Changing the VRF of an interface on XE will remove all IPv4/v6 addresses from that interface. To change it on XR, you must remove all IPv4/v6 addresses manually, remove/change the VRF, then add the IPv4/v6 addresses back along with the new VRF (if desired).

```
! XRv3
interface Loopback101
 vrf OSPF
 ipv4 address 192.101.13.13 255.255.255.255
 ipv6 address ::192:101:13:13/128
```

```
! CSR5
interface Loopback101
 vrf forwarding OSPF
 ip address 192.101.5.5 255.255.255.255
 ipv6 address ::192:101:5:5/128
```

38.1.2 OSPF and sham-links

Both OSPFv2 and OSPFv3 can be used as on both XE and XR as a PE-CE routing protocol. In a traditional environment where the CE routing is not running a VRF, the PE routing would run the OSPF process inside of the customer VRF while the CE would run OSPF in the global routing table. Using VRF-Lite on the CE, both sites will be running it in a VRF. Because the configurations for PE and CE are very similar up to this point, only one of each is shown. CSR5 is a CE and XRv2 is a PE. OSPFv3 instance numbers are shown here just for variety and have nothing to do with VRF-Lite; the value is link-local and must match on a segment for a neighbor to form. This is true whether OSPFv3 is inside a VRF or the global table.

```
! CSR5
interface GigabitEthernet2.101
```

```

vrf forwarding OSPF
ip ospf network point-to-point
ip ospf 101 area 0
ospfv3 network point-to-point
ospfv3 101 ipv6 area 0 instance 12

router ospfv3 101
  address-family ipv6 unicast vrf OSPF

router ospf 101 vrf OSPF

! XRv2
interface GigabitEthernet0/0/0/0.101
  vrf OSPF

router ospf 101
  router-id 0.0.101.12
  vrf OSPF
    area 0
    interface GigabitEthernet0/0/0/0.101
      network point-to-point

router ospfv3 101
  router-id 0.0.101.12
  vrf OSPF
    area 0
    interface GigabitEthernet0/0/0/0.101
      network point-to-point
      instance 12

```

Assuming we replicate these configurations appropriately on all 8 devices (all PEs and CEs), we should have OSPFv2/v3 neighbors everywhere. For brevity, we will verify this from the PE side only on the 4 PE routers. Notice that we do not need to specify an AFI for XR's OSPFv3; the IPv4 AFI is not supported for OSPFv3 on XR, so IPv6 is assumed. We see 4 OSPFv2 and 4 OSPFv3 neighbors, so we can assume that OSPFv2/v3 is working properly.

```

R3#show ip ospf 101 neighbor | include FULL
0.0.101.14      0    FULL/  -          00:00:38    192.3.101.14    Gig2.101

192.12.101.6    1      FULL/ -      00:00:37      12      Gig0/0/0/0.101

```

Next, we will quickly check to see if each PE learned OSPFv2/v3 routes from the CE. Each CE has a loopback with a single route. We will check CSR3 and XRv1 only. CSR3 learns the IPv4 and IPv6 routes from XRv4 and XRv1 does the same from XRv3.

```

R3#show ip route vrf OSPF ospf | begin Gate
Gateway of last resort is not set
O      192.101.14.14
      [110/2] via 192.3.101.14, 14:09:56, GigabitEthernet2.101

R3#show ipv6 route vrf OSPF ospf | begin Application
a - Application
O      ::192:101:14:14/128 [110/1]
      via FE80::14, GigabitEthernet2.101

RP/0/0/CPU0:XRv1#show route vrf OSPF ospf
O      192.101.13.13/32 [110/2] via 192.11.101.13, 14:14:37,
GigabitEthernet0/0/0/0.101

RP/0/0/CPU0:XRv1#show route vrf OSPF ipv6 ospf
O      ::192:101:13:13/128
      [110/1] via fe80::13, 14:14:19, GigabitEthernet0/0/0/0.101

```

Next, we must configure bidirectional redistribution between OSPF and BGP. OSPF to BGP allows customers routes to be advertised via VPNv4/v6 (and have labels allocated) to remote BGP peers. Redistributing from BGP into OSPF allows the received BGP routes to be learned by the customer. We will show the configuration on CSR3 and XRv1 only. The connected redistribution on OSPFv3 isn't a requirement, but IOS platforms automatically exclude connected routes when redistributing IPv6 protocols.

```

! CSR3
router bgp 214
 address-family ipv4 vrf OSPF
   redistribute ospf 101

 address-family ipv6 vrf OSPF

```

```

        redistribute ospf 101 include-connected

router ospfv3 101
  address-family ipv6 unicast vrf OSPF
    redistribute bgp 214

router ospf 101 vrf OSPF
  redistribute bgp 214 subnets

! XRv1
router bgp 214
  vrf OSPF
    rd 214:101
    address-family ipv4 unicast
      redistribute ospf 101

    address-family ipv6 unicast
      redistribute ospfv3 101

router ospf 101
  vrf OSPF
    redistribute bgp 214

router ospfv3 101
  vrf OSPF
    redistribute bgp 214

```

At this point, the PEs should have the locally redistributed routes inside their BGP tables, as well as the remote iBGP routes from the remote peer. Both PEs can see the loopbacks of XRv3 and XRv4, the CEs, within the BGP table. This verifies that the OSPF to BGP redistribution was successful at both ends.

```

R3#show bgp vpnv4 unicast vrf OSPF | include 1[34]\.1[34]
  *>i 192.101.13.13/32 214.0.0.11          2      100      0 ?
  *> 192.101.14.14/32 192.3.101.14       2          32768 ?

RP/0/0/CPU0:XRv1#show bgp vpnv4 unicast vrf OSPF | include 1[34]\.1[34]
  *> 192.101.13.13/32 192.11.101.13       2          32768 ?

  *> ::192:101:13:13/128
  *>i::192:101:14:14/128

```

To verify that the BGP to OSPF redistribution worked, we can check the local OSPF LSDB on each PE to look for the Type 3 (for IPv6) or Type 5 LSA (for IPv4). The reason for the discrepancy is discussed later. For now, we can see that the redistribution worked.

```
R3#show ip ospf 101 database | include Link_States|13\.13

```

At this point, one would assume there is full reachability between sites. The tricky part about using OSPF with VRF-Lite on the CEs is the notion of the down bit (DN bit). The PEs will set this bit on LSA3 and LSA5 routes redistributed from BGP which help control the “flow” of the LSA. The idea is that when backdoor links exist, the LSA originated at one PE is flooded to a second PE. That second PE should never install this route as it could create suboptimal routing at best, or a loop at worst. Examining a remote prefix (redistributed from BGP to OSPF locally) on CSR3, we can see the “downward” bit in the LSA options field. IOS routers only recently started setting the DN-bit in their LSA5 as it used to only happen for LSA3. The older mechanism for LSA5 loop-prevention was to use route tags, which still happens for backwards compatibility. Converting the route tag below to hex yields 0xD00000D6, and converting the last 2 bytes back into decimal yields the BGP AS number, which is 214. The output is almost identical for XRv1, as the DN-bit is set and the route-tag represents BGP AS 214.

```
R3#show ip ospf 101 database external 192.101.13.13
OSPF Router with ID (192.3.101.3) (Process ID 101)

```

If a router is running OSPF inside of a VRF, it automatically assumes that it is a PE for an MPLS network. On CSR6, we can see this by looking at the OSPF summary information for OSPFv2 and v3. This output isn't available on XR, but the assumption is the same, as XRv3 and XRv4 also thinks they are MPLS PEs. These VRF-Lite CE routers clearly are not MPLS PEs and are not connected to the MPLS superbackbone.

```
R6#show ip ospf 101 | include VPN
    Connected to MPLS VPN Superbackbone, VRF OSPF

R6#show ospfv3 vrf OSPF ipv6 | include VPN
    Connected to MPLS VPN Superbackbone
```

The result of this is that all of the CE routers will learn these LSA3/LSA5 inside their LSDBs, but cannot install them in the routing table. Neither CSR6 nor XRv4 make any mention that the LSA has the routing bit set, which means it is not candidate for RIB entry.

```
R6#show ip ospf 101 database external 192.101.13.13
    OSPF Router with ID (192.4.101.6) (Process ID 101)
    Type-5 AS External Link States
    LS age: 1511
    Options: (No TOS-capability, DC, Downward)

    External Route Tag: 3489661142
```

The same is true for the IPv6. CSR6 and XRv4 both learn the LSA3 but cannot install it in their RIB. They assume they are MPLS L3VPN PE routers since OSPF is inside a VRF, so installing this route could cause a loop.

```
RP/0/0/CPU0:XRv4#show ospfv3 vrf OSPF database inter-area prefix
::192:101:13:13/128
      OSPFv3 Router with ID (0.0.101.14) (Process ID 101 VRF OSPF)

```

To solve this problem, we need to notify OSPF that it is running inside of a VRF-Lite environment and to ignore the DN bit. The two essentially mean the same thing, and I phrase it this way because XE and XR have different syntaxes. XE is consistent using the “capability vrf-lite” syntax for both OSPFv2 and v3. XR is less consistent since it uses “capability vrf-lite” for OSPFv3 and “disable-dn-bit-check” for OSPFv2. On XE only, applying this command will reset the OSPFv2/v3 neighbors.

```
! CSR6
router ospfv3 101
address-family ipv6 unicast vrf OSPF
  capability vrf-lite

router ospf 101 vrf OSPF
  capability vrf-lite

! XRv4
router ospf 101
  vrf OSPF
  disable-dn-bit-check

router ospfv3 101
  vrf OSPF
  capability vrf-lite
```

In most of the outputs seen below, the routing bit will now be set on the LSA3/LSA5 on the CE routers. The DN-bit is still being set by the PEs, but the CEs are ignoring it entirely. Oddly, the routing bit output does not appear on the XE LSAs at all, which used to happen in older IOS versions. XR clearly displays it, as shown below.

```
R6#show ip ospf 101 database external 192.101.13.13

```

Quickly checking the routes on CSR6, we can see all the routes are installed to the remote loopbacks. Notice that some are external and some are inter-area. Specifically, the routes reachable via the XR PEs are external, and the route via the CSR PE is inter-area. These discrepancies are resolved later.

```

R6#show ip route vrf OSPF | include 192.101
    192.101.5.0/32 is subnetted, 1 subnets

```

Looking into the BGP routing information for VPNv4 on a PE, we see there are several new extended communities used by BGP when transporting OSPF routes inside of an L3VPN. Specifically, the routes from the XE PE have a domain-ID encoded in them. The domain-ID type is 0x0005, which is the default in IOS platforms, and the value 0x0065 converted to decimal is 101. This is where the OSPF PID has global significance; it is used by default to seed the domain-ID for an MPLS L3VPN. XR makes no assumptions and does not encode this extended community by default. We can see this by checking the iBGP next-hops of each route and seeing the difference. The routes from XRv1 and XRv2 don't include this domain ID by default.

```

```

When the domain-IDs match at remote ends of a VPN, they are considered to be in the same “AS” so to speak. The MPLS network acts like a “super backbone” as a third level of hierarchy greater than area 0. This allows area 0 networks to be bridged together and see one another as inter-area. When the domain-ID does not match, BGP makes no assumptions about this continuity and treats the routes as external when redistributing them. If one router has a domain-ID and the other does not, this is considered a non-match. We could set the domain-ID to be the same as we saw above on the routes from CSR3, but for variety, we will change it to a new value of 244 (0xF4) so that we can demonstrate the change on XE platforms as well. We quickly verify that the configuration is correct by checking the OSPF process details. For now, we will limit this change only to OSPFv2 processes on the PEs.

```

! CSR4
router ospf 101 vrf OSPF
  domain-id type 0005 value 000000F40200

! XRv1
router ospf 101
  vrf OSPF
    domain-id type 0005 value 000000F40200

R4#show ip ospf 101 | include Domain
  Domain ID type 0x0005, value 0x000000F40200

```

```
RP/0/0/CPU0:XRv1#show ospf vrf OSPF | begin Domain
Primary Domain ID:
0x5:0x000000f40200
[snip]
```

Now, all routes learned by CSR4 will have the same domain-ID. Provided these extended communities match the local domain-ID (verified above), then the routes are considered inter-area.

```

We can verify this worked by checking the CE routers to ensure all of their OSPF routes are inter-area. Notice that CSR6 shows 8 inter-area routes and 0 external type-2 routes, which is what we had before. XRv4 doesn't show 0 external routes, it just displays nothing except the inter-area routes, which is an implicit verification method.

```
R6#show ip route vrf OSPF summary | section ospf 101
ospf 101          5          3          0          768          2336
  Intra-area: 0  Inter-area: 8  External-1: 0  External-2: 0
  NSSA External-1: 0  NSSA External-2: 0
```

```
RP/0/0/CPU0:XRv4#show route vrf OSPF summary detail | begin ospf 101
ospf 101          7          7          0          0
```

Inter-area:	7	7	0	0
Total	12	12	1	1

The concept is identical for IPv6 routes. The only difference is that suddenly XE no longer makes assumptions about the domain-ID. At this point, neither XE nor XR PEs will encode a domain-ID since neither of them consider the OSPF PID as a seed value.

```

Checking the local domain-IDs on CSR4 and XRv1, we see that there are no defaults. Personally, I prefer the XR behavior because it never makes a domain-ID assumption and is consistent between OSPFv2 and OSPFv3. XE makes assumptions about the OSPFv2 domain-ID only by using the OSPF PID, which is inconsistent.

```
R4#show ospfv3 vrf OSPF | include Domain
Domain ID (none)
```

```
RP/0/0/CPU0:XRv1#show ospfv3 vrf OSPF | begin Domain
[no output]
```

Since there are no domain-IDs carried in any VPNv6 routes and also no local domain-IDs, OSPF makes the bold assumption that the routes are indeed in the same domain. This behavior is in accordance with RFC 4577 and is not a Cisco-specific behavior. We can confirm this on CSR6 and XRv4. At this point, we could consider our configuration “complete” since all of the OSPFv2/v3 CE routers see one another’s routes as inter-area (not external).

```
R6#show ipv6 route vrf OSPF summary | section ospf 101
```

```
ospf 101      8      1152      1664
  Intra-area: 0  Inter-area: 8  External-1: 0  External-2: 0
  NSSA External 1: 0  NSSA External 2: 0
```

```
RP/0/0/CPU0:XRv4#show route vrf OSPF ipv6 summary detail | begin ospf 101
```

```
ospf 101      7      7      0      0
  Inter-area: 7      7      0      0
Total      12      12      1      1
```

We will first configure the domain-ID on all of the XE PEs only, this time using value 246 (0xF6). This should introduce some external routes into the VPN routing tables since routes from CSR3 and CSR4 will have domain-IDs. XRv1 and XRv2 will not; this behavior would mimic the original issue observed with OSPFv2 where XE PEs added domain-IDs but XR PEs did not. After configuring the feature, we confirm it on both routers.

```
! CSR3 and CSR4
router ospfv3 101
  address-family ipv6 unicast vrf OSPF
    domain-id type 0005 value 000000F60200
```

```
R3#show ospfv3 vrf OSPF | include Domain
Domain ID 0x000000F60200, type 0x0005
```

```
R4#show ospfv3 vrf OSPF | include Domain
Domain ID 0x000000F60200, type 0x0005
```

Checking CSR4, we can see that VPNv6 prefixes from CSR3 have this new domain-ID, which matches the local domain-ID, and therefore means routes from CSR3 will be inter-area. Routes from the remote XR PEs have no domain-ID, and are therefore external. Both CSR6 and XRv14 now see a mix of inter-area and external routes.

```

  Inter-area: 5          5          0          0
  External-2: 2          2          0          0
Total            12          12          1          1
```

If we look at the specific routes that are still external, we see that the PE-CE transit links connected to XRv1 and XRv2 are the only ones. For whatever reason, XRv1 and XRv2 did not set the domain-ID on those routes during redistribution, possibly because they were not OSPF-learned. XE is smarter than XR in this regard and considers those are part of the OSPFv3 domain, even as connected routes. I am not able to find a workaround for this since the RPL does not contain a mechanism to manually set this extended community. At least we know that the OSPF-learned routes, which are much more important and relevant, have the extended community applied and the feature is working properly. Inter-area reachability to the transit links is not important, so XR's inability to add the domain-ID to these VPNv6 prefixes is insignificant.

```
R6#show ipv6 route vrf OSPF | include E2

      Extended community: OSPF route-type:0:2:0x0 OSPF router-id:214.0.0.12
RT:214:101
```

It is worth discussing the other new extended communities and OSPF domain-ID types. First, the OSPF route-type is something not present in normal OSPF/BGP architectures. The attribute carries the same information for both IPv4 and IPv6 routes. XE and XR display them a little differently but the premise is the same. The first 32 bits represent the area-ID, which is 0 in this case (XR shows 0 and XE shows 0.0.0.0). The next 8 bits specify the route type: 1 or 2 for intra-area routes (whether it came from LSA1 or LSA2), 3 for inter-area, 5 for external, and 7 for NSSA-external. The creators of this extended community kept it simple by using the same numbers as the OSPF LSA types. Below, we can see two area 0 routes with route-type 2. Although we don't have any DRs in the network, I am not sure why the route-type is 2 and not 1, but we at least know it is intra-area. The last field of the route-type is the options field, which is 8 bits, and is used to signal information about external routes. Since neither route was external, these flags are 0 (XR shows 0x0 and XE shows 0).

```
RP/0/0/CPU0:XRv1#show bgp vpnv4 unicast vrf OSPF 192.101.6.6/32 | include
Extended
```

```
Extended community: OSPF domain-id:0x5:0x000000f40200 OSPF route-  
type:0:2:0x0 OSPF router-id:192.4.101.4 RT:214:101
```

```
R4#show bgp vpnv6 unicast vrf OSPF ::192:101:14:14/128 | include OSPF_RT  
OSPF ROUTER ID:192.3.101.3:0 OSPF RT:0.0.0.0:2:0
```

The area-ID value is 0 for external routes as well. To see this, we will create a new loopback on CSR6 and redistribute it into OSPFv2 and v3.

```
! CSR6  
interface Loopback600  
description EXTERNAL TEST  
vrf forwarding OSPF  
ip address 192.60.6.6 255.255.255.255  
ipv6 address ::192:60:6:6/128  
  
route-map RM_CONN_TO_OSPF permit 10  
match interface Loopback600  
  
router ospfv3 101  
address-family ipv6 unicast vrf OSPF  
redistribute connected route-map RM_CONN_TO_OSPF  
  
router ospf 101 vrf OSPF  
redistribute connected subnets route-map RM_CONN_TO_OSPF
```

We can verify the redistribution was successful by checking the local LSDB. Note: The PEs must be configured to match external routes when redistributing from OSPF into BGP. This is not allowed by default and must be explicitly specified. Because there are no external routes on CSR5 or XRv3, we only need to configure external redistribution on CSR3 and CSR4.

```
R6#show ip ospf 101 database external self-originate | include Link|Mask  
Type-5 AS External Link States  
LS Type: AS External Link  
Link State ID: 192.60.6.6 (External Network Number )  
Network Mask: /32
```

```
R6#show ospfv3 vrf OSPF database external self-originate | include Prefix  
Prefix Address: ::192:60:6:6  
Prefix Length: 128, Options: None
```

```
! CSR3 and CSR4  
router bgp 214  
address-family ipv6 vrf OSPF  
redistribute ospf 101 include-connected match internal external  
  
address-family ipv4 vrf OSPF
```

```
redistribute ospf 101 match internal external
```

When we check the route on XRv1, we can see the route-type is 5 to signal an external route. The lower-order bit of the options byte is set to 1 which indicates external type-2.

```
RP/0/0/CPU0:XRv1#show bgp vpnv4 unicast vrf OSPF 192.60.6.6/32 | include
Extend
      Extended community: OSPF domain-id:0x5:0x000000f40200 OSPF route-
type:0:5:0x1 OSPF router-id:192.4.101.4 RT:214:101
```

When the route is external type-1, the options field is clear, and the route-type remains 5. We update the route-map to make this change, then tell OSPFv2/v3 to perform the redistribution again to capture the changes. XRv1 shows the new route-type. Also note there is no need to carry the OSPF metric in a new extended community as it is already carried in the MED value. This is standard BGP behavior when redistributing from an IGP, and OSPF can use that to keep metrics consistent across the L3VPN.

```
! CSR6
route-map RM_CONN_TO_OSPF permit 10
  set metric-type type-1

R6#clear ip ospf 101 redistribution
R6#clear ospfv3 vrf OSPF redistribution
```

```
RP/0/0/CPU0:XRv1#show bgp vpnv4 unicast vrf OSPF 192.60.6.6/32 | include
Extend
      Extended community: OSPF domain-id:0x5:0x000000f40200 OSPF route-
type:0:5:0x0 OSPF router-id:192.4.101.4 RT:214:101
```

The OSPF RID community needs no explaining. It contains the OSPF RID of the originating PE for the route in question. Looking at CSR6 and XRv4 loopbacks side by side from XRv2's perspective, we can see different OSPF RID's since the egress PEs differ for those two prefixes.

```
RP/0/0/CPU0:XRv2#show bgp vpnv4 unicast vrf OSPF 192.101.14.14 | include
Extend
      Extended community: OSPF domain-id:0x5:0x000000f40200 OSPF route-
type:0:2:0x0 OSPF router-id:192.3.101.3 RT:214:101

RP/0/0/CPU0:XRv2#show bgp vpnv4 unicast vrf OSPF 192.101.6.6 | include Extend

type:0:2:0x0 OSPF router-id:192.4.101.4 RT:214:101
```

The domain-ID types are just meant to be differentiators between various domain-ID formats. The Cisco default is 0x005, as we saw earlier. All four domain-ID formats (0x0005, 0x0105, 0x0205, 0x8005) are 8 bytes long where the first 2 bytes always represent the type. Type 0x0005 uses the next 2 bytes for the "global administrator" field and the last 4 for the "local administrator" field, which is where the OSPF

PID is encoded. Types 0x0105 and 0x0205 use 4 bytes for global and 2 bytes for local, but the difference is really just cosmetic. You can set the actual value to whatever is necessary to make the OSPF routes appear the way they need to (sometimes you may want inter-area, sometimes external). The 0x8005 type is exceptional; using 0x8005 is a way to achieve backward compatibility between all domain-ID types. When this domain-ID type is used, the first 2 bytes are ignored, so the domain-ID types no longer need to match. It is a raw bit-for-bit comparison of the remaining 6 bits, which works perfectly for backwards compatibility. We will configure XRv1 with a domain-ID type of 0x8005 but use the same ID value of 0xF4 for OSPFv2.

```
! XRv1
router ospf 101
 vrf OSPF
  domain-id type 8005 value 000000F40200
```

XRv4 still sees the route to XRv3 as inter-area, which proves that CSR3 ignored the difference between 0x0005 and 0x8005.

```

```

We will quickly test type 0x8005 on XE using OSPFv3. Changing CSR3's domain-ID to 0x8005, XRv2 still considers it within the same domain since the low-order 6-byte domain value still matches. CSR5 still sees the route as inter-area, as we expect.

Let's assume that between XRv4 and CSR6, and XRv3 and CSR5, that we have installed a pair of low-speed backdoor links. These could be non-MPLS private WAN leased lines that we want to use only for backup, while preferring the L3VPN MPLS path via the PEs primarily. The backdoor link configuration is not shown, but we can quickly check the neighbors on all four CEs for both IPv4/v6 to verify the neighbor was formed properly. We also increase the cost of this link to a very high value in an attempt to prefer MPLS. The backdoor link is Gig2.201 on XE or Gig0/0/0/0.201 on XR and has a cost of 500. We can quickly verify this on CSR6 and XRv4 as an example. Notice that there is 1 neighbor on the link also, as expected. This serves as a quick check to verify the cost configuration and OSPFv2/v3 neighbors.

When we check the routing table on CSR6, we can see that it is preferring the slow backdoor link over the fast MPLS connection. This is because the backdoor route is intra-area, and is always preferred over inter-area. This OSPF “route preference” behavior cannot be modified and the problem persists for both IPv4 and IPv6. Assigning a different area to the transit link would not work as this would imply bridging area 0 over a non-backbone area. Technically this is possible with virtual links and other awkward workarounds, but that is beyond the scope of this problem.

The aptly-named “sham-link” can be used to solve this problem. Like a virtual-link, it will connect two non-adjacent OSPF speakers using a demand-circuit that allows LSAs to be exchanged across the network. Sham-link routers must be in the same domain (same or compatible domain-ID type with identical domain-ID value). The sham-link can be used to connect two L3VPN PEs together over an MPLS core to create an intra-area link between them. This would form a square between the PEs and CEs, which would allow the OSPF cost to be the deciding factor in terms of routing. To build a sham link, we must create host-route loopbacks (/32 for IPv4 and /128 for IPv6) which exist inside of the same VPN as the process we intend to bridge. The loopbacks must be advertised into BGP and must not be advertised into the VRF-aware OSPF process; the purpose is to create reachability between these endpoints over the MPLS network, not the customer network. We will configure OSPFv2 and OSPFv3 sham-links between CSR3 and CSR4 first. Note that even if we were using OSPFv3 for the IPv4 AFI, the sham-link endpoint must be a /128 IPv6 address. We can advertise the sham-links into BGP via network statements or redistribution; it does not matter. We will use both methods for variety.

```
! CSR3
interface Loopback101
  description SHAM LINK ENDPOINT
  vrf forwarding OSPF
  ip address 101.0.0.3 255.255.255.255

  match interface Loopback101

router bgp 214
  address-family ipv4 vrf OSPF
    redistribute connected route-map RM_SHAM_TO_BGP

  address-family ipv6 vrf OSPF
```

```
redistribute connected route-map RM_SHAM_TO_BGP
```

Before configuring the sham-link itself, we should verify that we have connectivity between these sham-link endpoints. The traffic will be MPLS-encapsulated since it is inside a VPN as these look like ordinary VPNv4/v6 routes with BGP allocated labels. We only need to perform the ping test from one PE since the return traffic (echo-reply) confirms bidirectional connectivity.

```
R3#show bgp vpnv4 unicast vrf OSPF | include 101.0.0.[34]
*> 101.0.0.3/32      0.0.0.0          0          32768 i
*>i 101.0.0.4/32      214.0.0.4         0          100      0 ?

Packet sent with a source address of 101.0.0.3
!!!!!!
Success rate is 100 percent (5/5), round-trip min/avg/max = 7/8/10 ms
```

We quickly perform the same verification for the IPv6 sham-link endpoints. Connectivity is achieved via 6VPE, the technique we have been using for ordinary IPv6 L3VPN connectivity.

```
R3#show bgp vpnv6 unicast vrf OSPF | include ::101:0:0:[34]
*> ::101:0:0:3/128   ::              0          32768 i
*>i ::101:0:0:4/128   ::FFFF:214.0.0.4

R4#show bgp vpnv6 unicast vrf OSPF | include ::101:0:0:[34]
* i ::101:0:0:3/128   ::FFFF:214.0.0.3
*> ::101:0:0:4/128   ::              0          32768 ?

R3#ping vrf OSPF ::101:0:0:4 source ::101:0:0:3
Type escape sequence to abort.
Sending 5, 100-byte ICMP Echos to ::101:0:0:4, timeout is 2 seconds:
Packet sent with a source address of ::101:0:0:3%OSPF
!!!!!!
Success rate is 100 percent (5/5), round-trip min/avg/max = 2/2/3 ms
```

Although technically not required, we should ensure that these new loopbacks do not get advertised into the customer OSPF process. Because OSPF is redistributing from BGP without a filter at present, the OSPF process will contain these as external routes. We can manually filter them out on both CSR3 and CSR4. There is no reason to expose these addresses to the customer.

```
! CSR3 and CSR4
ip prefix-list PL_SHAM_ENDPOINTS seq 10 permit 101.0.0.0/8 ge 32
```

```

route-map RM_BGP_TO_OSPF_V4 deny 10

ipv6 prefix-list PL_SHAM_ENDPOINTS seq 5 permit ::101:0:0:0/80 ge 128
route-map RM_BGP_TO_OSPF_V6 deny 10
  match ipv6 address prefix-list PL_SHAM_ENDPOINTS
route-map RM_BGP_TO_OSPF_V6 permit 1000

router ospf 101
  redistribute bgp 214 subnets route-map RM_BGP_TO_OSPF_V4

router ospfv3 101
  address-family ipv6 unicast vrf OSPF
  redistribute bgp 214 route-map RM_BGP_TO_OSPF_V6

```

We can verify this was successful by checking the local LSDBs for any external routes beginning with 101.0.0.X or ::101:0:0:X. We don't see any. The reason we see IPv6 externals is due to the XR behavior earlier about failing to add the domain-ID to connected redistributed routes. The point is that the sham-link endpoints do not exist as external OSPFv2/v3 routes, which means the customer cannot learn them.

```

```

Next, we will configure the sham-link. We can optionally specify the OSPF cost as well, and provided this cost (plus the cost of the PE-CE transit links) is less than the backdoor cost, we can prefer MPLS over the backdoor. We will use a cost of 214 on the OSPFv2 sham-link without authentication. On the OSPFv3 sham-link, we use the default cost of 1, but enable authentication for variety. Older version of IOS do not allow for sham-link authentication, so we test that in XE for OSPFv3 only. For brevity, only CSR3 is

shown, but the CSR4 configuration is identical with reversed IPv4/v6 addresses for the sham-link endpoints.

```
! CSR3
key chain KC_SHAM_AUTH
  key 1
    key-string SHAM_AUTH
    cryptographic-algorithm hmac-sha-512

router ospf 101 vrf OSPF
  area 0 sham-link 101.0.0.3 101.0.0.4 cost 214

router ospfv3 101
  address-family ipv6 unicast vrf OSPF
    area 0 sham-link ::101:0:0:4 ::101:0:0:3 authentication key-chain
    KC_SHAM_AUTH
```

You cannot use MD5 authentication with OSPFv3 sham-links and must use one of the SHA options.
Failure to specify a valid option inside the key chain will results with some error messages.

```
! CSR3
%OSPFv3-5-NOCRYPTOALG: Key ID 1 in key chain KC_SHAM_AUTH does not have a
valid cryptographic algorithm
%OSPFv3-4-NOVALIDKEY: No valid authentication key under key-chain
KC_SHAM_AUTH
```

Assuming the configuration is correct, the routers will generate syslog messages to indicate that the sham-links are up. In case we miss these messages, we can check the status of the sham-links with a special show command. The pertinent information includes the fact that it is a demand-circuit with suppressed hellos. The DNA bit is allowed which implies the link is DC-capable, which is an LSA option in the LSA1. The link is considered point-to-point, which is a link type within the LSA1 as well. This is different than the virtual-link, which has its own link type in the LSA1. The sham-link is graphically equivalent to an ordinary point-to-point link. That is why we can explicitly specify a sham-list cost, but we cannot explicitly specify a virtual-link cost.

```

```

To verify the topological significance of the sham-link, we will inspect the LSA1 from the perspective of CSR3. Most of the output is removed, but we can see a new link inside the LSA1. It uses a link address of 0.0.0.24, which is a new software IDB generated by the router specifically for the sham-link. XE allows us to see this new interface number for confirmation as well. The link is point-to-point and has a cost of 214 as expected. If we didn't know a sham-link was being used, this LSA1 output is indistinguishable from an ordinary OSPF P2P link using IP unnumbered.

```

```

Because the CEs share area 0 with the PEs, they can see this new link in the OSPF graph. Like the MPLS-TE forwarding-adjacency, they use this in their SPF calculations. CSR6 now routes over MPLS to reach XRv4's loopback. The total OSPF path cost is 217. A cost of 1 represents the local PE-CE hop, 214 for the sham-link, 1 more for the remote PE-CE hop, and 1 more for the loopback itself. Of greatest significance is the route-type, which is now intra-area. The routes that were once inter-area, as defined by being in the same domain, are now bridged into the same area by the sham-link. A virtual-link connects a disjoint area 0 over a non-backbone OSPF area while a sham-link connects a disjoint area 0 over MPLS. The IPv6 route is similar, but has a metric of 3 to account for the two PE-CE links and the sham-link default cost of 1. The cost of the IPv6 loopback is 0 compared to the IPv4 loopback cost of 1.

```

A quick traceroute from CSR6 proves that the sham-link is working correctly. Traffic is being routed towards the L3VPN PEs and encapsulated inside MPLS.

```
R6#traceroute vrf OSPF 192.101.14.14 source 192.101.6.6
Type escape sequence to abort.

To verify that there is no disruption to the customer network, we will verify that the sham-link endpoints did not leak into the customer RIB. This should be impossible given the filtering we configured earlier, but we will ensure the routes do not exist. This makes the sham-link entirely transparent to the customer CE devices.

```

```
RP/0/0/CPU0:XRv4#show route vrf OSPF ipv6 | include ::101
[no output]
```

The same exact problem presents itself on the other side of the network with XRv1 and XRv2 as PEs. XRv3 prefers the high-cost backdoor link because the route to CSR5's loopback is intra-area via that path.

```

RP/0/0/CPU0:XRv3#show route vrf OSPF 192.101.5.5
Routing entry for 192.101.5.5/32
  Known via "ospf 101", distance 110, metric 501, type intra area
  Routing Descriptor Blocks
    192.5.101.5, from 192.12.101.6, via GigabitEthernet0/0/0/0.201
      Route metric is 501
  No advertising protos.

```

The concepts for sham-links in XR are exactly the same and the configuration is similar. First, we will create the loopbacks on XRv1 and XRv2 inside of the customer VPN. Then, we advertise them into BGP using a network statement or redistribution. XR does not support the “match interface” or anything equivalent within RPL, so we can minimize RPL configuration using parameters.

```

! XRv1
interface Loopback101
  description SHAM LINK ENDPOINT
  vrf OSPF
  ipv4 address 101.0.0.11 255.255.255.255

redistribute connected route-policy RPL_SHAM_TO_BGP(PS_SHAM_V4)

address-family ipv6 unicast
redistribute connected route-policy RPL_SHAM_TO_BGP(PS_SHAM_V6)

```

We will verify that these routes were successfully advertised into BGP on both PEs. Notice that the remote sham-link endpoints from CSR3 and CSR4 are also learned; they are still inside the iBGP advertisement space. This allows us to build sham-links to CSR3 and CSR4 if we desire, but since there are no east-to-west backdoor links, there is little reason to do so. We can see all 4 routes from all 4 PEs within IPv4 and IPv6 scopes.

```

RP/0/0/CPU0:XRv1#show bgp vpnv4 unicast vrf OSPF | include 101.0.0
*>i101.0.0.3/32      214.0.0.3      0      100      0 i

```

We verify reachability between these XRv1/XRv2 sham-link endpoints, again relying on basic MPLS L3VPN (6VPE) connectivity. This is exactly the same procedure we followed for the XE sham-link.

```

RP/0/0/CPU0:XRv1#ping vrf OSPF 101.0.0.12 source 101.0.0.11
Type escape sequence to abort.
Sending 5, 100-byte ICMP Echos to 101.0.0.12, timeout is 2 seconds:
!!!!
Success rate is 100 percent (5/5), round-trip min/avg/max = 1/20/89 ms

RP/0/0/CPU0:XRv1#ping vrf OSPF ::101:0:0:12 source ::101:0:0:11
Type escape sequence to abort.
Sending 5, 100-byte ICMP Echos to ::101:0:0:12, timeout is 2 seconds:
!!!!
Success rate is 100 percent (5/5), round-trip min/avg/max = 1/1/1 ms

```

Like last time, we should remove these sham-link endpoints from OSPF. Notice that XRv2 is originating XRv1's sham-link endpoint and vice versa; they are learning one another's BGP routes then redistributing them back into OSPF. Fortunately, the DN-bit protects the PEs from installing these

routes, but it is still bad design and may be confusing for customers, who will install these routes. XRv1, for example, has these new loopbacks inside of OSPFv3.

```
RP/0/0/CPU0:XRv1#show ospfv3 vrf OSPF database | include ::101:0:0:1[12]
0.0.101.11      141      0x80000001  ::101:0:0:12/128
214.0.0.12      81       0x80000001  ::101:0:0:11/128
```

To correct it, we can use RPL to filter any sham-link endpoints when redistributing from BGP to OSPF. The prefix-lists we used above on XRv2 can be re-used for this task again and are not shown again. They must be copied to XRv1 since only XRv2 has them configured at present (XRv1 used network statements instead). Using a new RPL policy along with parameterization, we instruct OSPF to filter any sham-link endpoints from entering from BGP. The filter also accounts for CSR3/CSR4 sham-link endpoints as well. For this reason, when there are many PEs in an OSPF-serving L3VPN, the sham-link endpoints should aggregate nicely to simplify this filtering task.

```
! XRv1 and XRv2
route-policy RPL_BGP_TO_OSPF($SHAMS)
  if destination in $SHAMS then
    drop
  else
    pass
  endif
end-policy

router ospf 101
  vrf OSPF
  redistribute bgp 214 route-policy RPL_BGP_TO_OSPF(PS_SHAM_V4)

router ospfv3 101
  vrf OSPF
  redistribute bgp 214 route-policy RPL_BGP_TO_OSPF(PS_SHAM_V6)
```

To verify it, we can check XRv1 for any 101.0.0.X or ::101:0:0:X routes. Now, we don't see any in the PE LSDBs or in the customer routing tables.

```
RP/0/0/CPU0:XRv1#show ospfv3 vrf OSPF database | include ::101:0:0:
[no output]
```

```
RP/0/0/CPU0:XRv1#show ospf vrf OSPF database | include 101.0.0
[no output]
```

```
RP/0/0/CPU0:XRv3#show route vrf OSPF ipv4 | include 101.0.0
[no output]
```

```
RP/0/0/CPU0:XRv3#show route vrf OSPF ipv6 | include ::101
[no output]
```

Next, we will configure the sham-link. The sham-link has its own stanza in XR, which is convenient because it has many sub-options like authentication and cost. We will set a custom cost and enable basic MD5 authentication on the OSPFv2 sham-link. The OSPFv3 sham-link will be more secure with IPSec encryption using DES and SHA-1 hash. For brevity, only XRv1's configuration is shown since the only difference on XRv2 is reversing the IPv4/v6 addresses.

```
! XRv1
router ospf 101
  vrf OSPF
  area 0
    sham-link 101.0.0.11 101.0.0.12
      cost 12
      authentication message-digest
      message-digest-key 1 md5 SHAM_AUTH

router ospfv3 101
  vrf OSPF
  area 0
    sham-link ::101:0:0:11 ::101:0:0:12
      encryption ipsec spi 1212 esp des clear 1234567890abcdef authentication
      sha1 clear 12345678901234567890123456789012345678901234567890
```

Like any other OSPFv2/v3 neighbor, we will see a log message for the sham-links, along with the numbers allocated to them. Unlike XE, XR allocates different numbers for different sham-links between processes. XE assigned both SLs a value of 0 on CSR3 and CSR4 because the OSPF processes are entirely different.

```
! XRv1
ospfv3[1028]: %ROUTING-OSPFv3-5-ADJCHG : Process 101, Nbr 214.0.0.12 on
OSPF_SL1 from LOADING to FULL, Loading Done
ospf[1018]: %ROUTING-OSPF-5-ADJCHG : Process 101, Nbr 214.0.0.12 on OSPF_SL0
in area 0 from LOADING to FULL, Loading Done, vrf OSPF vrfid 0x60000007
```

In case you miss the log messages, the XR show commands give the same details as the XE show commands. We verify that the link is a demand-circuit, point-to-point, suppressing hellos, has the proper cost/authentication, and is operational.

```
RP/0/0/CPU0:XRv1#show ospf vrf OSPF sham-links

```

Next, we will confirm that the link exists within the router LSA on XRv2 for both OSPFv2 and OSPFv3. We can see that the OSPFv2 link has a cost of 12, is point-to-point, is DC-capable, and connects directly to XRv1. The OSPFv3 link has all the same attributes except uses a cost of 1, the default. Just like ordinary OSPF P2P interfaces, the costs need not be symmetric, but for simplicity, I configure them so.

```

RP/0/0/CPU0:XRv2#show ospf vrf OSPF database router self-originate
    OSPF Router with ID (214.0.0.12) (Process ID 101, VRF OSPF)

[snip]
Link connected to: another Router (point-to-point)
Link Metric: 1
Local Interface ID: 2
Neighbor Interface ID: 2
Neighbor Router ID: 0.0.101.11

```

Because XRv3 and CSR5 can use this sham-link in their SPF calculations, the MPLS network is considered intra-area and its cost is can be directly compared to the slow backdoor. XRv3 now routes to CSR5's loopback via MPLS. The total cost is 15: 1 for the local PE-CE link, 12 for the sham-link, 1 for the remote PE-CE link, and 1 for the loopback. The type is intra-area as expected. The output is similar for IPv6 with a different metric based on the IPv6 topology and sham-link cost.

```

RP/0/0/CPU0:XRv3#show route vrf OSPF 192.101.5.5

    Route metric is 3
  No advertising protos.

```

Traceroute confirms the proper traffic pattern. XR does not show the labels for IPv6, possibly due to a cosmetic adjustment, but we can see the 214.X.X.X address which represents the MPLS core. There is no possibility of this IPv6 traceroute working without MPLS encapsulation, so we can safely assume the traffic was labeled.

```

RP/0/0/CPU0:XRv3#traceroute vrf OSPF 192.101.5.5 source 192.101.13.13

```

For good measure, we will use TCL to verify reachability from CSR5 and CSR6 to all endpoints for both AFIs. XR technically supports TCL, but is very complicated and not mentioned in this chapter. We will therefore limit the TCL verifications to XE CE routers. The outputs from CSR5 and CSR6 are not shown, but the pings were 100% successful to all destinations. Notice the OSPF “external” test prefixes are included here also.

```
! CSR5 and CSR6
tclsh
foreach x {
192.101.5.5
192.101.6.6
192.101.13.13
192.101.14.14
192.60.6.6
::192:101:5:5
::192:101:6:6
::192:101:13:13
::192:101:14:14
::192:60:6:6
} { ping vrf OSPF $x source loopback101 repeat 3 timeout 1 }
```

38.1.3 EIGRP and Site-of-Origin (SoO)

EIGRP is another option for PE-CE routing with L3VPN. The VRF-aware EIGRP configuration is almost identical for IPv4 and IPv6, assuming we used named-mode on the XE platforms. There is no “DN-bit” concept in EIGRP, so the VRF-lite configuration is not much different from the PE, with the exception of BGP redistribution. For EIGRP IPv6, there is no “network” statement, so all IPv6-enabled interfaces are automatically configured for EIGRP. They can selectively disabled by shutting them down under the EIGRP process as needed, but in our case, we don’t need to disable EIGRP IPv6 from any interfaces. The configurations for CSR5 and XRv3 are shown for brevity. The backdoor link is Gig2.202; it exists between XRv4/CSR6 and XRv3/CSR5 and is currently shut down. Note that XR does not log EIGRP neighbor changes by default, so I personally enable this feature at all times to assist with troubleshooting.

```
! CSR5
router eigrp VPN
 address-family ipv4 unicast vrf EIGRP autonomous-system 102
   network 192.0.0.0 0.255.255.255

 address-family ipv6 unicast vrf EIGRP autonomous-system 102

! XRv3
router eigrp VPN
 vrf EIGRP
 address-family ipv4
```

```

router-id 13.13.13.13
log-neighbor-changes
autonomous-system 102
interface Loopback102
  passive-interface
interface GigabitEthernet0/0/0/0.102
interface GigabitEthernet0/0/0/0.202

address-family ipv6
router-id 13.13.13.13
log-neighbor-changes
autonomous-system 102
interface Loopback102
  passive-interface
interface GigabitEthernet0/0/0/0.102
interface GigabitEthernet0/0/0/0.202

```

We quickly verify the neighbors are up on all EIGRP PEs for both AFIs. We only expect to see one neighbor on each PE, which is the corresponding CE.

```

0  Link Local Address:   Gi0/0/0/0.102    11 05:40:54     1    200   0   90
   fe80::5

```

We verify that CSR4 and XRv2 learn some EIGRP routes from CSR6 and CSR5 in both IPv4 and IPv6 AFIs. In this case, there is a single loopback from each CE, just like there was for OSPF. This confirms the CE-to-PE route exchange.

```
R4#show ip route vrf EIGRP eigrp | begin Gateway
Gateway of last resort is not set
    192.102.6.0/32 is subnetted, 1 subnets

    [90/10880] via fe80::5, 05:46:31, GigabitEthernet0/0/0/0.102
```

These EIGRP routes are redistributed from EIGRP into BGP, and vice versa, on all four PEs. The configurations on CSR4 and XRv2 are shown; they are identical to the VRF-aware CE configurations with the addition of redistribution discussed earlier.

```
! CSR4
router eigrp VPN
 address-family ipv4 unicast vrf EIGRP autonomous-system 102
   topology base
   redistribute bgp 214

 address-family ipv6 unicast vrf EIGRP autonomous-system 102

   redistribute bgp 214

! XRv2
router eigrp VPN
 vrf EIGRP
   address-family ipv4
     redistribute bgp 214

   address-family ipv6
     redistribute bgp 214
```

When we verify the routes inside of VPNv4/v6, we see that there are several new extended communities attached to them. The cost-community has a dedicated section and is not discussed in

detail, but notice that the point of insertion (POI) is pre-bestpath, which is value 128. XE decodes this for us but XR does not. The second 128 represents the community-ID which allows cost-communities to be compared directly, not to be confused with the POI value of 128 meant to indicate pre-bestpath evaluation. When used in this fashion, the cost-community always uses POI and community ID values of 128; this cannot be modified. The metric value is easy to read and is directly derived from the RIB metric of 10880.

```
R4#show ip route vrf EIGRP 192.102.6.6 | include metric
  Known via "eigrp 102", distance 90, metric 10880, type internal
    Route metric is 10880, traffic share count is 1
```

```
RP/0/0/CPU0:XRv2#show route vrf EIGRP ipv4 192.102.5.5/32 | include metric
  Known via "eigrp 102", distance 90, metric 10880, type internal
    Route metric is 10880
```

The other extended-community values are EIGRP-specific and are encoded according to the table below.

Attribute	Type	Usage	Value
General	0x8800	Route information	Route flag and tag
Metric	0x8801	Route metric and AS	ASN and delay
	0x8802	Route metric	Reliability, next-hop, bandwidth
	0x8803	Route metric	Reserve, Load, and MTU
External	0x8804	External route metric	Remote AS and Remote ID
	0x8805	External route metric	Remote Protocol and Remote Metric
Originating RID	0x8806	Originating RID	Originating RID

```

```

There isn't much reason to deep-dive the extended communities, but we will verify the values for sanity once. XR makes it a little easier by naming the communities by their purpose. 0x8800 carries the "route-flag" which is 0x8000 (32768) and the route-tag (not set) on both routes. 0x8801 carries the AS number (102) and the route delay (288). We can check the EIGRP topology on both routers to confirm a value of 288, which is the delay in tens of microseconds scaled by 256 (11,250,000 picoseconds * 256 = 2,880,000,000 picoseconds = 2880 microseconds).

```
R4#show eigrp address-family ipv4 vrf EIGRP topology 192.102.6.6/32
EIGRP-IPv4 VR(VPN) Topology Entry for AS(102)/ID(192.4.102.4)
      Topology(base) TID(0) VRF(EIGRP)
EIGRP-IPv4(102): Topology base(0) entry for 192.102.6.6/32
      State is Passive, Query origin flag is 1, 1 Successor(s), FD is 1392640,
RIB is 10880
      Descriptor Blocks:
      192.4.102.6 (GigabitEthernet2.102), from 192.4.102.6, Send flag is 0x0
      Composite metric is (1392640/163840), route is Internal
      Vector metric:
      Minimum bandwidth is 1000000 Kbit
      Total delay is 11250000 picoseconds
      [snip]
```

Verifying 0x8802 is also somewhat tricky. The first 2 byte value contains both the reliability and next-hop flag together. 65281 translates to 0xFF01, which represents a reliability of 255 and a hop count of 1.

```
R4#show eigrp address-family ipv4 vrf EIGRP topology 192.102.6.6/32 | include
Reliab|Hop
      Reliability is 255/255
      Hop count is 1
```

Extended community 0x8802 carries the link bandwidth of 2560. This appears to be measured in hundreds of megabits scaled by 256 (1,000,000,000 bps * 256 = 256,000,000,000 bps, = 256 Gbps).

```
R4#show eigrp address-family ipv4 vrf EIGRP topology 192.102.6.6/32 | include
bandw
      Minimum bandwidth is 1000000 Kbit
```

The extended community 0x8803 has a decimal value of 65281 which we know evaluates to 0xFF01. The load represents the 1, and I assume the "Reserved" field is set to 0xFF. XR seems to set this to zero, though, so it is probably ignored. The route MTU is clearly shown as a decimal value of 1500, which is convenient.

```
R4#show eigrp address-family ipv4 vrf EIGRP topology 192.102.6.6/32 | include
MTU|Load
      Load is 1/255
```

Minimum MTU is 1500

The decimal number carried in 0x8806 by CSR4 is 0xC0046606 in hex. This translates to 192.4.102.6, while XRv2 shows CSR5's loopback in reverse order. This is the originating router's EIGRP RID. We can quickly confirm this by checking the topology information. Ideally both RIDs would be the loopback, but since they are not manually set, EIGRP selecting the first available interface at the time I configured it. For external routes, this is an important field for loop prevention.

```
R4#show eigrp address-family ipv4 vrf EIGRP topology 192.102.6.6/32 | include Origin
```

```
Originating router is 192.4.102.6
```

```
RP/0/0/CPU0:XRv2#show eigrp vrf EIGRP ipv4 topology 192.102.5.5/32 | include Origin
```

```
Originating router is 192.102.5.5
```

These extended communities are automatically and by default added to BGP routes when EIGRP is redistributed from within a VPN. The reason all this information is necessary is so that routes across the VPN, assuming the ASN matches, can be considered internal. The MPLS network essentially collapses to a single node in the EIGRP topology and can be used to seamlessly bridge EIGRP islands. This is somewhat like a sham-link except zero cost and in-band, whereas the sham-link was an explicit, out-of-band link with an associated OSPF cost (it was part of the graph). As is normal for any IGP to BGP redistribution, the IGP metric is also copied into the BGP MED. Checking XRv2, we can see the IGP metric inside the BGP MED, which is installed in the local routing table as an iBGP route.

```
RP/0/0/CPU0:XRv2#show route vrf EIGRP ipv4 192.102.6.6/32 | include metric
```

```
Known via "bgp 214", distance 200, metric 10880, type internal
```

```
Route metric is 10880
```

Checking the EIGRP topology on CSR5, we can see all of the original routing information from CSR6's loopback is preserved across the L3VPN. The hop count is only two, since the MPLS network (including the PEs) only counts as 1 hop. The originating router is still the same, and the reported distance (RD) of 1392640 is the FD of the remote PE (CSR4). This proves that the MPLS network is viewed as a single hop; because it's one hop, it looks like one router, and thus has no cost. The PE-CE link costs are accounted for, however. For OSPF, the sham-link itself incurred a cost of at least 1.

```
R5#show eigrp address-family ipv4 vrf EIGRP topology 192.102.6.6/32
```

Composite_metric
  Composite metric is (1392640/163840), route is Internal

```

We can disable the extended community population on CSR4 by telling EIGRP not to pass this information to BGP on a per AFI basis. Notice that the normal BGP redistribution actions still occur: the IGP metric is copied to the BGP MED, the export route-target is imposed, and an MPLS label is allocated. The VPN can still work, but the remote PEs will not be able to assume this route is part of the same EIGRP AS as its local customer.

```

! CSR4
router eigrp VPN
  address-family ipv4 unicast vrf EIGRP autonomous-system 102
  no populate bgp-ext-comm

R4#show bgp vpnv4 unicast vrf EIGRP 192.102.6.6/32 | begin Local
Local
  192.4.102.6 (via vrf EIGRP) from 0.0.0.0 (214.0.0.4)

sourced, best
  Extended Community: RT:214:102
  mpls labels in/out 4035/nolabel
  rx pathid: 0, tx pathid: 0x0

```

As soon as this happens, XRv2 prints out an angry syslog message. The message warns us that during the BGP to EIGRP redistribution, we did not set a metric. Normally this is required when redistributing into EIGRP (except when using connected, static, or other EIGRP routes). We didn't set a metric earlier because the extended-communities handled that for us. Now, without any extended-community information, EIGRP cannot accept this route since it has no idea what the seed metric should be.

```

! XRv2
eigrp[1002]: %ROUTING-EIGRP-3-NO_REDISTMETRIC : EIGRP-VPN: EIGRP-v4 102: No
metric set while redistributing route 192.102.6.6/32

```

```

RP/0/0/CPU0:XRv2#show eigrp vrf EIGRP ipv4 topology 192.102.6.6/32
% IPv4-EIGRP (VRF EIGRP): Route not in topology table of EIGRP VPN.

```

To solve it, we will set a bogus set of default metric inputs on XRv1 and XRv2 for EIGRP IPv4. The route is very much external now as the extended-community enhancements were removed, but at least EIGRP can see it. Last, we can check the routing on CSR5 to ensure it installs this route. The bogus metrics make the external routes stand out very clearly.

```
! XRv1 and XRv2
router eigrp VPN
 vrf EIGRP
  address-family ipv4
  default-metric 12345 543 234 123 1500
```

```

```

```
R5#show ip route vrf EIGRP eigrp | section include EX
  D - EIGRP, EX - EIGRP external, O - OSPF, IA - OSPF inter area
D EX    192.102.6.6
        [170/3200022] via 192.12.102.12, 00:03:13, GigabitEthernet2.102
```

One of the pitfalls of disabling extended-community support on CSR4 is that it has bidirectional implications. That is to say, not only will EIGRP not instruct BGP to carry the information, but it also will not honor information from BGP, either. On CSR4, it learns CSR5's loopback via iBGP and it has all of the extended-community values. However, the route does not exist in the EIGRP topology since, like XRv2, there is no default redistribution metric and EIGRP is now blind to these extended-communities.

```
R4#show bgp vpnv4 unicast vrf EIGRP 192.102.5.5/32 bestpath | begin Local
Local
214.0.0.12 (metric 20) (via default) from 214.0.0.12 (214.0.0.12)
  Origin incomplete, metric 10880, localpref 100, valid, internal, best
  Extended Community: RT:214:102 Cost:pre-bestpath:128:10880
```

```

    Topology(base) TID(0) VRF(EIGRP)
%Entry 192.102.5.5/32 not in topology table

```

To fix this, we will set an easily-visible default-metric on CSR4 as well. Like on XRv2, the route is now external and locally originated by CSR4. Any EIGRP speakers behind CSR4 in the customer VPN will not know there is another EIGRP process across MPLS in this configuration.

```

! CSR4
router eigrp VPN
  address-family ipv4 unicast vrf EIGRP autonomous-system 102
  topology base
  default-metric 112347 10203 100 200 1499

R4#show eigrp address-family ipv4 vrf EIGRP topology 192.102.5.5/32
EIGRP-IPv4 VR(VPN) Topology Entry for AS(102)/ID(192.4.102.4)
    Topology(base) TID(0) VRF(EIGRP)
EIGRP-IPv4(102): Topology base(0) entry for 192.102.5.5/32
  State is Passive, Query origin flag is 1, 1 Successor(s), FD is 6692471435
  Descriptor Blocks:
  214.0.0.12, from Redistributed, Send flag is 0x0
    Composite metric is (6692471435/0), route is External
  Vector metric:
    Minimum bandwidth is 112347 Kbit
    Total delay is 102030000000 picoseconds
    Reliability is 100/255
    Load is 200/255
    Minimum MTU is 1499
    Hop count is 0
    Originating router is 192.4.102.4
  External data:
    AS number of route is 214
    External protocol is BGP, external metric is 10880
    Administrator tag is 0 (0x00000000)

```

Unlike CSR5, who only saw one external route, CSR6 will see all routes as external since the router not supporting extended-communities is its local PE (CSR4). We will ensure CSR6 has the route for CSR5's loopback and test reachability.

```

R6#show ip route vrf EIGRP eigrp | section 5\.5
D EX    192.102.5.5
        [170/52290053] via 192.4.102.4, 00:03:25, GigabitEthernet2.102

```

192.102.13.0/32 is subnetted, 1 subnets

```
R6#ping vrf EIGRP 192.102.5.5 source 192.102.6.6
Type escape sequence to abort.

!!!!!!
Success rate is 100 percent (5/5), round-trip min/avg/max = 6/7/11 ms
```

The capability to disable this is identical for IPv6. Before we disable it, we will quickly verify that both CSR5 and CSR6 IPv6 loopbacks have the proper extended communities on XRv2. There is a new community, 0x8807, and it is so confusing that XR doesn't even know what to call it. The hex values decode into 80:169:171:0:0:0 which is meaningless at first sight. The important thing is the communities are being passed.

```

XRv2 learns this route, but is unable to redistribute it into EIGRP as there is no default-metric specified. The EIGRP-v6 process on XRv2 didn't give us a log message this time, so we must be aware of EIGRP redistribution behavior with respect to unspecified seed metrics. We can confirm that other VPNv6 routes, like XRv4's loopback, did get redistributed from BGP into EIGRP successfully. For that route, all of the extended-communities were properly interpreted as the hop count is 1 (the MPLS network is one EIGRP router) and the route is internal.

```
RP/0/0/CPU0:XRv2#show bgp vpnv6 unicast vrf EIGRP ::192:102:6:6/128 | begin

```

```
RP/0/0/CPU0:XRv2#show eigrp vrf EIGRP ipv6 topology ::192:102:6:6/128
% IPv6-EIGRP (VRF EIGRP): Route not in topology table of EIGRP VPN.
```

```
RP/0/0/CPU0:XRv2#show eigrp vrf EIGRP ipv6 topology ::192:102:14:14/128
IPv6-EIGRP VR(VPN) AS(102) VRF EIGRP: Topology entry for ::192:102:14:14/128
  State is Passive, Query origin flag is 1, 1 Successor(s), FD is 1377280,
RIB is 10760
  Routing Descriptor Blocks:
    ::ffff:214.0.0.3, from VPNv6 Sourced, Send flag is 0x0
      Composite metric is (1377280/0), Route is Internal (VPNv6 Sourced)
      Vector metric:
        Minimum bandwidth is 1000000 Kbit
        Total delay is 11015625 picoseconds
        Reliability is 255/255
        Load is 1/255
        Minimum MTU is 1500
        Hop count is 1
      Originating router is 14.14.14.14
```

To solve it, we will hardcode a metric to the BGP redistribution, rather than set a default metric. This is accomplished with an RPL and cannot be placed in-line as XE allows.

```
! XRv1 and XRv2
route-policy RPL_BGP_TO_EIGRP
  set eigrp-metric 111111 222 33 44 1455
end-policy

router eigrp VPN
  vrf EIGRP
```

```
address-family ipv6
  redistribute bgp 214 route-policy RPL_BGP_TO_EIGRP
```

The significant downside of this hardcoded-metric approach is that, unless specific prefixes are matched in the RPL, all of the EIGRP metrics will be modified in this way, overriding the legitimate extended-community values. This does allow CSR6's loopback to enter the EIGRP topology, but also overrides the values for XRv4's loopback. Fortunately, the EIGRP ASN is still honored so the route remains internal.

```
RP/0/0/CPU0:XRv2#show eigrp vrf EIGRP ipv6 topology ::192:102:6:6/128
IPv6-EIGRP VR(VPN) AS(102) VRF EIGRP: Topology entry for ::192:102:6:6/128
  State is Passive, Query origin flag is 1, 1 Successor(s), FD is 151388165,
  RIB is 1182720
```

Routing Descriptor Blocks:

```
::ffff:214.0.0.4, from Redistributed, Send flag is 0x0
  Composite metric is (151388165/0), Route is External
  Vector metric:
    Minimum bandwidth is 111111 Kbit
    Total delay is 2220000000 picoseconds
    Reliability is 33/255
    Load is 44/255
    Minimum MTU is 1455
    Hop count is 0
  External data:
    Originating router is 214.0.0.12 (this system)
    AS number of route is 102
    External protocol is BGP, external metric is 10880
    Administrator tag is 0 (0x00000000)
```

```
RP/0/0/CPU0:XRv2#show eigrp vrf EIGRP ipv6 topology ::192:102:14:14/128
IPv6-EIGRP VR(VPN) AS(102) VRF EIGRP: Topology entry for ::192:102:14:14/128
  State is Passive, Query origin flag is 1, 1 Successor(s), FD is 1377280,
  RIB is 1182720
```

Routing Descriptor Blocks:

```
::ffff:214.0.0.3, from VPNv6 Sourced, Send flag is 0x0
  Composite metric is (151388165/0), Route is Internal (VPNv6 Sourced)
  Vector metric:
    Minimum bandwidth is 111111 Kbit
    Total delay is 2220000000 picoseconds
    Reliability is 33/255
    Load is 44/255
    Minimum MTU is 1455
    Hop count is 1
```

A quick routing table check on CSR5 confirms that both routes are installed with the appropriate route types as verified in the EIGRP topology. They have the same RIB metric, which is probably not desirable.

```
R5#show ipv6 route vrf EIGRP eigrp | section include :6:6|:14:14
EX ::192:102:6:6/128 [170/1187840]
```

```

        via FE80::12, GigabitEthernet2.102
D   ::192:102:14:14/128 [90/1187840]
        via FE80::12, GigabitEthernet2.102

```

To fix it, we can modify the RPL on XRv1/XRv2 to target these routes. Since we cannot match on the presence or absence of the cost-community or any advanced EIGRP communities, we can match the next-hop of CSR4 to capture all prefixes easily. Be sure to identify this address as an IPv4-compatible IPv6 address; even though XR displays VPNv6 next-hops within the preceding “::FFFF:”, they are IPv6 next-hops. Notice that now only CSR6’s loopback, the only true external route, is marked as “Redistributed” with a bogus metric while the other routes are “VPNv6 Sourced” with the correct metric. Both the summary and detailed outputs are shown below.

```

! XRv1 and XRv2
route-policy RPL_BGP_TO_EIGRP
  if next-hop in (::FFFF:214.0.0.4) then
    set eigrp-metric 111111 222 33 44 1455
  else
    pass
  endif
end-policy

```

```

```

As we know, CSR4 is now ignoring the extended-community values that XRv2 advertised inside of CSR5's loopback, so connectivity will be broken as it was for IPv4. CSR4 is totally ignoring all BGP-carried EIGRP extended-communities.

```
R4#show eigrp address-family ipv6 vrf EIGRP topology ::192:102:5:5/128
EIGRP-IPv6 VR(VPN) Topology Entry for AS(102)/ID(192.4.102.4)
Topology(base) TID(0) VRF(EIGRP)
%Entry ::192:102:5:5/128 not in topology table
```

We will use the same destructive approach on CSR4 by setting the metric within the redistribute statement. Using “default-metric” was a more appropriate solution as it respects the extended-communities, if they exist.

```
! CSR4
route-map RM_BGP_TO_EIGRP permit 10
set metric 55555 444 33 22 1411

router eigrp VPN
address-family ipv6 unicast vrf EIGRP autonomous-system 102
topology base
redistribute bgp 214 route-map RM_BGP_TO_EIGRP
```

```
R4#show eigrp address-family ipv6 vrf EIGRP topology ::192:102:5:5/128
EIGRP-IPv6 VR(VPN) Topology Entry for AS(102)/ID(192.4.102.4)
Topology(base) TID(0) VRF(EIGRP)

State is Passive, Query origin flag is 1, 1 Successor(s), FD is 302776437
Descriptor Blocks:
::FFFF:214.0.0.12, from Redistributed, Send flag is 0x0
```

```

Composite metric is (302776437/0), route is External
Vector metric:
  Minimum bandwidth is 55555 Kbit
  Total delay is 4440000000 picoseconds
  Reliability is 33/255
  Load is 22/255
  Minimum MTU is 1411
  Hop count is 0
External data:
  Originating router is 192.4.102.4 (this system)
  AS number of route is 214
  External protocol is BGP, external metric is 10880
  Administrator tag is 0 (0x00000000)

```

As expected, since CSR4 is the one not supporting the extended-communities, all remote routes are viewed as external, so there is little sense in matching specific entities in the route-map as all routes will have the same suboptimal appearance. The topology lists these as “redistributed” as opposed to “VPNv6 Sourced”.

```

R4#show eigrp address-family ipv6 vrf EIGRP topology | section include ::192
P ::192:102:14:14/128, 1 successors, FD is 302776437

P ::192:102:6:6/128, 1 successors, FD is 1392640
    via FE80::6 (1392640/163840), GigabitEthernet2.102
P ::192:102:5:5/128, 1 successors, FD is 302776437
    via Redistributed (302776437/0)

```

To achieve full reachability, I must instruct XRv1 to perform the same metric manipulations as XRv2 in order for its EIGRP VPN process to redistribute CSR6’s loopback from VPNv4/v6 (configuration not shown since it is identical). We quickly verify that XRv3 has the routes and that they are of the proper type.

```

RP/0/0/CPU0:XRv3#show route vrf EIGRP ipv4 eigrp | include 192.102.
D 192.102.5.5/32 [90/16000] via 192.11.102.11, 02:08:13,

GigabitEthernet0/0/0/0.102
D 192.102.14.14/32 [90/15880] via 192.11.102.11, 1d07h,
GigabitEthernet0/0/0/0.102

```

```

RP/0/0/CPU0:XRv3#show route vrf EIGRP ipv6 eigrp | include ::192:102:
D ::192:102:5:5/128
D EX ::192:102:6:6/128
D ::192:102:14:14/128

```

Likewise on CSR3, it needs to set metrics for routes coming from CSR4 only, since it can honor the extended-communities from XRv1 and XRv2. The configuration for EIGRP-v4 is identical using the default-metric under the EIGRP AFI. The IPv6 configuration varies slightly to account for only adjusting metrics from CSR4. Since XE doesn't support in-line matches like XR does, we define an IPv6 prefix-list with an IPv4-compatible IPv6 address representing CSR4's VPNv6 endpoint. We quickly check the routes on XRv4 to ensure it learned all routes and that their route-types are correct. If "default-metric" cannot be used, using route-maps/RPL in this way can retain the EIGRP metrics for internal routes and seed new ones for external routes.

```
! CSR3
ipv6 prefix-list PL_IPV6_NHOP_CSR4 seq 5 permit ::FFFF:214.0.0.4/128

route-map RM_BGP_TO_EIGRP permit 10
  match ipv6 next-hop prefix-list PL_IPV6_NHOP_CSR4
  set metric 55555 444 33 22 1411
route-map RM_BGP_TO_EIGRP permit 1000

RP/0/0/CPU0:XRv4#show route vrf EIGRP ipv4 eigrp | include 192.102.

D EX ::192:102:6:6/128
D    ::192:102:13:13/128
```

For completeness, we will advertisement an external route to the MPLS network by redistributing a new loopback on CSR5, much like we did for OSPF. We cannot use CSR6 again because it's PE is not capable of encoding the extended-communities. We also cannot use anything inside 192.0.0.0/8 due to CSR5's network statement.

```
! CSR5
interface Loopback500
  description EXTERNAL TEST EIGRP
  vrf forwarding EIGRP
  ip address 50.50.5.5 255.255.255.255
  ipv6 address ::50:50:5:5/128

route-map RM_CONN_TO_EIGRP permit 10
  match interface Loopback500

router eigrp VPN
  address-family ipv4 unicast vrf EIGRP autonomous-system 102
```

```
topology base
  redistribute connected route-map RM_CONN_TO_EIGRP
```

```
address-family ipv6 unicast vrf EIGRP autonomous-system 102
topology base
  redistribute connected route-map RM_CONN_TO_EIGRP
```

XRv12 learns this route but has some new extended-communities. We can check the EIGRP topology to try and decode the values.

```
RP/0/0/CPU0:XRv2#show bgp vpnv4 unicast vrf EIGRP 50.50.5.5/32
[snip]
  Local
    192.12.102.5 from 0.0.0.0 (214.0.0.12)
      Origin incomplete, metric 10880, localpref 100, weight 32768, valid,
      redistributed, best, group-best, import-candidate
      Received Path ID 0, Local Path ID 1, version 695
      Extended community: COST:128:129:10880 EIGRP route-info:0x0:0 EIGRP
      AD:102:288 EIGRP RHB:255:1:2560 EIGRP LM:0x0:1:1500 EIGRP AR:0:192.102.5.5
      EIGRP PM:11:0 RT:214:102
```

The first 0 represents the remote AS, which is 0 per the EIGRP topology (route was redistributed from “connected”). The next 4 bytes represents the originator ID, which is CSR5’s loopback. The second community carries the remote protocol/metric; I assume 11 means “connected” and the remote metric of 0.

```
RP/0/0/CPU0:XRv2#show eigrp vrf EIGRP ipv4 topology 50.50.5.5/32 | begin
External data
  External data:
    Originating router is 192.102.5.5
    AS number of route is 0
    External protocol is Connected, external metric is 0
    Administrator tag is 0 (0x00000000)
```

A quick look at CSR3’s BGP and EIGRP tables shows similar information. XE is less friendly in decoding information, but converting 3227911429 to hex yields 0xC0660505, which is 192.102.5.5, which is the originator ID. This is important for loop prevention with EIGRP external routes, so transporting it is important.

```
R3#show bgp vpnv4 unicast vrf EIGRP 50.50.5.5/32
[snip]
  Local, (Received from a RR-client)
    214.0.0.12 (metric 30) (via default) from 214.0.0.12 (214.0.0.12)

```

Even though the route is external, carrying the extended-communities still allows the MPLS domain to carry the EIGRP metrics for the external route. XRv4 sees the router as two hops away with the proper vector metric information.

```
RP/0/0/CPU0:XRv3#show eigrp vrf EIGRP ipv4 topology 50.50.5.5/32

```

The last significant feature of EIGRP is the site-of-origin (SoO). This is an extended-community carried in a new EIGRP TLV that allows an administrator to identify an EIGRP “site”. A multi-homed site, such as one with backdoor links, might be susceptible to transient routing loops during EIGRP convergence. For example, if XRv4’s loopback fails, it would issue QUERY messages to CSR6 and CSR3 (assume there was a backdoor to CSR3). If CSR4, the remote PE, receives the QUERY before CSR3 has a chance to respond, it will REPLY affirmatively that there is an alternate path (the BGP route). Although count-to-infinity may eventually break the loop, this is not an ideal circumstance. SoO works like route-tags except is more dynamic and solves a very specific problem. Setting it on a PE-CE link on the PE side tells EIGRP to copy the SoO value into a BGP extended-community during redistribution. Below, we can see the new SoO community of 102:14 on CSR3.

```
! CSR3
route-map RM_EIGRP_SOO permit 10
  set extcommunity soo 102:14

interface GigabitEthernet2.102
  ip vrf sitemap RM_EIGRP_SOO

      rx pathid: 0, tx pathid: 0x0

```

When remote PEs receive this and perform redistribution back into EIGRP, this community is carried over again. Because CSR4 cannot understand these communities, it does not carry this information from BGP into EIGRP. This is consistent with its treatment of the EIGRP vector metrics as well.

```

R5#show eigrp address-family ipv4 vrf EIGRP topology 192.102.14.14/32 |
include SoO
  Extended Community: SoO:102:14

```

```

R6#show eigrp address-family ipv4 vrf EIGRP topology 192.102.14.14/32 |
include SoO
[no output]

```

```

RP/0/0/CPU0:XRv3#show eigrp vrf EIGRP topology 192.102.14.14/32 | begin Ext
  Extended Community:
    SoO:102:14

```

If another site (including CEs) have an SoO set on an interface, routes received that match the SoO are discarded. We cannot use the backdoor (currently shut down) between CSR6 and XRv4 since CSR4 does not support the extended-communities. Instead, we can configure XRv3 to be in the same “site” as XRv4. This means that XRv3 will not be able to learn routes marked with SoO:104:14 from the PE.

```

! XRv1
router eigrp VPN
  vrf EIGRP
    interface GigabitEthernet0/0/0/0.102
      site-of-origin 102:14

```

```

RP/0/0/CPU0:XRv3#show eigrp vrf EIGRP topology 192.102.14.14/32
% IPv4-EIGRP (VRF EIGRP): Route not in topology table of EIGRP VPN.

```

Notice that this is unlike a route-tag in that routes sent from XRv3 do not have the SoO set. This is set only on the redistribution from EIGRP into BGP, and used as an ingress filter for routes carrying the SoO TLV in EIGRP messages. XRv1 is not aware of any SoO configuration on XRv3 at all.

```
RP/0/0/CPU0:XRv1#show bgp vpnv4 unicast vrf EIGRP 192.102.13.13 | include

RT:214:102
```

If we bring up the backdoor link between CSR5 and XRv3 using Gig2.202 (not shown), XRv3 can still learn these routes via that link. Notice that the route still has the SoO set; CSR5 did not filter it since it does not have any SoO configurations that match that particular route.

```

SoO:102:14
```

A more realistic use of SoO is to prevent loops within the same site when a backdoor link is present. To do this, we can configure a number of different designs. We will examine the first using IPv4 and the third using IPv6; the second test case is difficult to verify and test.

1. Same SoO on the PEs, configured on the PE-CE link only. This is used so that the two sites have no reachability over MPLS whatsoever. If the two CE routers are actually in the same site, this design is very logical (the backdoor link is a high-speed LAN interface, for example).
2. Different SoO on the PE, configured on the PE-CE link only. This allows failover to occur but once a route comes “full circle” around the backdoor link, it is dropped at ingress on the PE that originally injected it, the route will be discarded. This prevents transient routing loops.
3. SoO X on the local CE’s backdoor link and the local PE’s PE-CE link. SoO Y on the remote CE’s backdoor link and the remote PE’s PE-CE link. This provides better protection than #2, still allows sites to communicate unlike #1, but provides less redundancy if the CE and backdoor routers are not the same device (that is to say, there is a larger EIGRP network in between the CE routers).

The first setup is very straightforward. Both PEs will use an SoO value for the PE-CE link. When the two sites exchange routes, the extended-communities are carried over BGP. We will configure this for the IPv4 AFI only, leaving the advanced example for IPv6. In XR, only one SoO can be applied per interface, per AFI.

```
! XRv1 and XRv2
router eigrp VPN
 vrf EIGRP
  address-family ipv4
    interface GigabitEthernet0/0/0/0.102
      site-of-origin 102:1212
```

In the ideal state, the entire MPLS network looks like a single EIGRP router, and so XRv2 prefers the BGP route to XRv1 versus the EIGRP route via CSR5. XRv1 adds the SoO and XRv2 sees it.

```

```

```
%Entry 192.102.13.13/32 not in topology table
```

We will bring the backdoor link up for our next test using IPv6. Here, we configure XRv3’s backdoor and XRv1 to be in one site, while CSR5’s backdoor and XRv2 are in another. This ensures that routes from a given site cannot re-enter the source site under any circumstances. It is loosely analogous to the “transit AS” prevention techniques used in BGP.

```
! XRv1

These routes are allowed to be learned by remote CEs as there is no SoO on the PE-CE link configured on the CE side. This allows MPLS to interconnect the two sites if the backdoor link fails. The EIGRP metrics have not been adjusted for any kind of route-preference, and the MPLS network does not qualify as a feasible successor, so we must use "all-links" to see the alternate paths when using the summary command.

```
R5#show eigrp address-family ipv6 vrf EIGRP topology all-links | section

```

We quickly shut down the backdoor link to verify MPLS WAN connectivity with traceroute. This allows to sites to have some form of redundancy with loop protection concurrently.

```
R5#traceroute vrf EIGRP ipv6
```

```
Target IPv6 address: ::192:102:13:13
```

```
Source address: ::192:102:5:5
```

```
[snip]
```

```
Tracing the route to ::192:102:13:13
```

```

1 FD00:192:12:102::12 3 msec 2 msec 2 msec
2 2001:214:11:12::11 [MPLS: Label 91018 Exp 0] 93 msec 6 msec 5 msec
3 ::192:102:13:13 94 msec 6 msec 6 msec

```

To demonstrate the loop protection, we will bring the backdoor link online and shutdown CSR5's PE-CE link. Because this PE-CE link was considered a connected route from CSR5's perspective, shutting down the link will remove this connected route. The link is still up on the PE, XRv2, so it will be redistributed into BGP and assigned SoO:102:12. XRv1 will advertise the PE-CE link from XRv2 to XRv3 since the SoO is SoO:102:11 and does not match XRv1's local SoO. XRv3 will do the same and advertise it to CSR5.

CSR5 should reject the route on ingress because its backdoor link is configured with SoO:102:12. This might reduce some redundancy if there were hosts on that LAN, or other networks directly connected to the PE; CSR5 would no longer have access. Unfortunately, the feature does not appear to work, and CSR5 is able to learn the route through the backdoor. I suspect that the “ip vrf sitemap” command doesn’t work on CEs for IPv6.

Because this test did not work, we will reverse the problem. We will bring CSR5’s link with XRv2 (PE) back up and shut down XRv3’s link to XRv1 (PE) instead. We will now we tracing the PE-CE link between XRv1 and XRv3. We first ensure that XRv1 creates the route, assigns SoO:102:11, and advertises it to XRv2. XRv2 should advertise it to CSR5, who should also see the SoO in the EIGRP topology.

```

Now, when CSR5 advertises the route to XRv3, the route is rejected. This proves that XR's implementation of SoO works correctly for IPv4 and IPv6, whereas XE only works reliably for IPv4.

```

RP/0/0/CPU0:XRv3#show eigrp vrf EIGRP ipv6 topology fd00:192:11:102::/64
% IPv6-EIGRP (VRF EIGRP): Route not in topology table of EIGRP VPN.

```

Before continuing, we will restore the PE-CE link on XRv3. Just like in the OSPF section, we will use TCL to verify full reachability from CSR5 and CSR6. The validation is not shown, but the script is below.

```

! CSR5 and CSR6
tclsh
foreach x {
192.102.5.5
192.102.6.6
192.102.13.13
192.102.14.14

```

```

50.50.5.5
::192:102:5:5
::192:102:6:6
::192:102:13:13
::192:102:14:14
::50:50:5:5
} { ping vrf EIGRP $x source loopback102 repeat 3 timeout 1 }

```

We will immediately notice the possibility of problems. A single PE (CSR4) routing not supporting the critical EIGRP extended communities can break many things. CSR4 thinks that the best path to CSR6's loopback is via XRv1, which is not true. Because this path has a relatively low pre-bestpath cost-community, it is compared against the local route's default value of 2147483648 (2^{31}) and is much better. If CSR4 supported the community, the cost-community on the local route would certainly be better.

```

To fix this problem, we must either re-enable the EIGRP extended-community processing on CSR4 or instruct BGP to ignore these communities entirely. We will choose the latter solution as it is more complicated. This feature cannot be modified on a per AF-basis and is global to the BGP process in its entirety. CSR4 will totally ignore the cost-community now, relying on the regular BGP best-path selection algorithm. Now, the local route is the best-path due to the weight attribute.

```
! CSR4
router bgp 214
  bgp bestpath cost-community ignore

R4#show bgp vpnv4 unicast vrf EIGRP 192.102.6.6/32 bestpath
[snip]
  Local
    192.4.102.6 (via vrf EIGRP) from 0.0.0.0 (214.0.0.4)
      Origin incomplete, metric 10880, localpref 100, weight 32768, valid,

      Extended Community: RT:214:102
      mpls labels in/out 4053/nolabel
      rx pathid: 0, tx pathid: 0x0
```

This still may not fix all of the problems in the network. In order for this to be effective, we would need to enable it everywhere, which would break many other things we tested. We will leave the EIGRP topology “broken” as a reference of how not to configure EIGRP over L3VPN. As a recommendation, either use cost-community everywhere or don’t use it anywhere. XRv1 is preferring XRv2 to reach CSR6 now, and advertises this as its bestpath to CSR4. Even though CSR4 is picking the proper route, the other routers are not. Manually manipulating the entire network to fix these issues is not worth it, so again, we leave the network broken.

```

```

As one final comment, EIGRP is capable of carrying SoO inside of external routes. Looking at 50.50.5.5/32, which was redistributed into EIGRP on CSR5, it carries the SoO from XRv2. When CSR3 redistributes it back into EIGRP, the SoO is carried with it as well. We won’t retest SoO for this specific route, but be aware that the SoO rules apply to all EIGRP routes that carry the SoO attribute.

38.1.4 IS-IS

IS-IS is not commonly used as PE-CE routing protocol as it is not common in enterprise (customer) networks. VRF-aware IS-IS is also not currently supported on XR, either, so demonstrating it in this topology is difficult. Additionally, IPv6 IS-IS is only supported in the XE global process. These limitations will drastically reduce the length of this section.

```
R3(config-subif)#ipv6 router isis 103
%ISIS: Cannot enable ISIS-IPv6 for non-default VRF process
```

```
R3(config-subif)#ipv6 router isis
%ISIS: Cannot enable ISIS-IPv6 for non-default VRF interface
```

The protocol itself does not support carrying SoO attributes nor is there is any concept of a sham-link for back-door protection. VRF-aware IS-IS is only enabled between CSR4 (PE) and CSR6 (CE) for a brief

demonstration. First, we verify the neighbor is up and IS-IS is operational. The configuration is identical to global-table IS-IS except the “vrf” keyword is included under the process. The PE configuration is shown below, which also redistributes from BGP.

```
! CSR4
router isis 103
 vrf ISIS
 net 49.0103.0000.0000.0004.00
 is-type level-2-only
 redistribute bgp 214
```

```
R4#show isis 103 neighbors
```

```
Tag 103:
```

System Id	Type	Interface	IP Address	State	Holdtime	Circuit Id
R6	L2	Gi2.103	192.4.103.6	UP	23	00

Because there is no remote IS-IS VPN, we will exchange VPN routes with CSR1 (central services) by importing RT:214:8. CSR8 will import RT:214:103 as well (not shown). Now, CSR6 will learn new routes via CSR4. We can see that all 15 routes are IS-IS Level 2 routes. The LSPDB shows that these are IP-External entries as part of CSR4’s LSP. Their metrics are 0 at the point of redistribution, much like loopbacks.

```

It is worth noting that when redistributing from IS-IS, the connected routes are not included. We confirm this on CSR4 by checking the VPNv4 table for the CSR4-CSR6 PE-CE link. We verify that CSR6’s loopback made it into the table, which is an IS-IS route on CSR4.

```

R4#show bgp vpnv4 unicast vrf ISIS 192.4.103.0/24
% Network not in table

R4#show bgp vpnv4 unicast vrf ISIS 192.103.6.6/32

```

Something interesting about SoO is that, when configured on a PE router, is entirely protocol-agnostic. IS-IS cannot carry nor interpret SoO, but routes learned on the PE-CE link can still have this community encoded when redistributing into BGP. We quickly test this on CSR4 by applying the SoO on the link towards CSR6 and checking the BGP VPNv4 table.

```

! CSR4

This could be used to filter routes advertised to CSR1 on CSR8 using BGP SoO, which is covered in detail later. Identifying this peer as being in the same “site” as CSR6 means that routes can no longer be exchanged within the IPv4 AFI. CSR8 cannot advertise CSR6’s loopback to CSR1 now, but it can import them locally.

```

Interestingly, because IS-IS does not understand SoO, CSR4 still freely redistributes CSR1's routes from BGP into IS-IS despite the SoO being the same. Selecting any route from CSR1, we can see the SoO is set and IS-IS appears to ignore it. CSR6 installs this route in its RIB as expected.

In the interest of keeping the network interesting, we will leave the IS-IS to BGP AS 82 connectivity broken intentionally. Removing the SoO from either CSR4's PE-CE link or CSR8's neighbor statement to CSR1 will restore connectivity. IS-IS was never designed to use SoO in this context but this lab illustrates the protocol-agnostic characteristics of SoO.

38.1.5 BGP and Site-of-Origin (SoO)

BGP is the simplest, most popular, most appropriate PE-CE routing protocol option. Traditionally, it is used between ASNs for inter-network routing, and MPLS L3VPN PE-CE is a perfect use-case. BGP's flexible filtering support, as well as SoO, make it the best option. It is also widely supported by service providers in real life since it is supported on all vendor platforms and is straightforward to implement in many cases. The configuration on CSR5 (CE) and XRv2 (PE) are shown below as a summary reference. Note that the backdoor connections are configured but in a shutdown state initially.

```
! CSR5
router bgp 104
 no bgp default ipv4-unicast

address-family ipv4 vrf BGP
 redistribute connected
 neighbor 192.5.104.13 remote-as 104

route-policy PASS in
route-policy PASS out

```

We quickly verify that the neighbors are up between PE-CE on these routers. The XR routers work well without needing to define multiple sessions for different AFs as the IPv6 next-hops are automatically adjusted. The verifications on the left-half of the network are not shown for brevity. The backdoor peer is marked as “Active” because XRv3 doesn’t have the peer shutdown, only CSR5 does, but the session is unable to form despite XRv3 attempting to establish it.

```

```

Because we are using the same basic MPLS L3VPN construct as we did for the other tests, we should see all of the customer VPN routes in each of the CE sites. The output above shows 0, which means the peer is up but no prefixes were received. We quickly check XRv2 to see if it is advertising routes to CSR5; it isn’t. XR is trying to be “smart” and not advertise routes to CSR5 that it knows will be dropped on ingress by the eBGP loop prevention mechanism. If a peer has AS X and AS X appears in the AS_PATH of a BGP route, it is highly likely that the peer will reject the routes on ingress.

```

RP/0/0/CPU0:XRv2#show bgp vrf BGP ipv4 unicast neighbors 192.12.104.5
advertised-routes
[no output]

```

Looking across the network to CSR3 and CSR4 as next-hops, we see that XRv2 has learned VPNv4 routes from those peers and imported them into the BGP VPN. Because they have AS 104 in the path, XR knows that CSR5 cannot accept this, and doesn’t even attempt to advertise it, as seen above.

```
RP/0/0/CPU0:XRv2#show bgp vpnv4 unicast vrf BGP | include 214.0.0.[34]
*>i192.3.104.0/24      214.0.0.3      0      100      0 104 ?

192.104.13.13/32	192.12.104.12	214.0.0.11	214 104?
192.104.14.14/32	192.12.104.12	214.0.0.3	214 104?

CSR5 still only has a set of local routes due to the loop prevention mechanism. Debugging BGP updates inbound on CSR5 reveals this. We expected this to happen once the PE started advertising the routes.

```
R5#show bgp vpnv4 unicast vrf BGP | begin Network
      Network      Next Hop      Metric LocPrf Weight Path
Route Distinguisher: 214:104 (default for vrf BGP)
*> 192.5.104.0      0.0.0.0      0      32768 ?
*> 192.12.104.0     0.0.0.0      0      32768 ?
*> 192.104.5.5/32   0.0.0.0      0      32768 ?
```

```
! CSR5
BGP(0): 192.12.104.12 rcv UPDATE about 192.5.104.0/24 -- DENIED due to: AS-
PATH contains our own AS;
BGP: 192.12.104.12 Modifying prefix 192.5.104.0/24 from 0 -> 4 address
```

There are two options to fix it. The first solution is CE-based. This will relax the loop-prevention rule by telling CSR5 to allow BGP routes with a certain number of the local-AS in the AS path. This is a number between 1 and 10 on both XE and XR platforms; the local-AS path can occur anywhere in the AS path up to the number of times we specify. The larger the number, the larger the possibility of a loop. The configurations for CSR5 are shown below which allows exactly 1 instance of AS 104 in the AS path of any received route from XRv2. After configuring it, we will ensure the configuration is applied properly to the neighbor. Because we have fixed the problem for IPv4 and IPv6, we will verify both concurrently.

```
! CSR5
router bgp 104
 address-family ipv4 vrf BGP
   neighbor 192.12.104.12 allowas-in 1

 address-family ipv6 vrf BGP
   neighbor FD00:192:12:104::12 allowas-in 1
```

```
R5#show bgp vpnv4 unicast vrf BGP neighbors 192.12.104.12 | include For
address|allow
```

```
For address family: VPNv4 Unicast
My AS number is allowed for 1 number of times
```

```
R5#show bgp vpnv6 unicast vrf BGP neighbors FD00:192:12:104::12 | include For
address|allow
```

```
For address family: VPNv6 Unicast
My AS number is allowed for 1 number of times
```

Now, we are able to learn all of the remote prefixes from the other BGP speakers. AS 104 is still in the path, but this is permitted one time. If a remote CE router applied AS path prepending to influence the SP's routing decision, this solution would not work without increasing the value up from 1.

```
R5#show bgp vpnv4 unicast vrf BGP | include 192.12.104.12
```

```
*> 192.3.104.0      192.12.104.12      0 214 104 ?
*> 192.4.104.0      192.12.104.12      0 214 104 ?
*> 192.6.104.0      192.12.104.12      0 214 104 ?
*> 192.11.104.0     192.12.104.12      0 214 104 ?
*> 192.104.6.6/32   192.12.104.12      0 214 104 ?
*> 192.104.13.13/32 192.12.104.12      0 214 104 ?
*> 192.104.14.14/32 192.12.104.12      0 214 104 ?
```

```
R5#show bgp vpnv6 unicast vrf BGP | begin Network
```

```
      Network      Next Hop      Metric LocPrf Weight Path
Route Distinguisher: 214:104 (default for vrf BGP)
*>  ::192:104:5:5/128
      ::           0           32768 ?
*>  ::192:104:6:6/128
      FD00:192:12:104::12
      0 214 104 ?
```

```
*> ::192:104:13:13/128
      FD00:192:12:104::12

[snip]
```

As a CE within the same VPN, XRv13 will have the same problem, but we can use an alternative solution. The second and most straightforward solution is to have the PE routers remark all instances of the customer AS number with the SP's AS number. That is, every instance of 104 in the AS path will be rewritten to 214 when advertised to the eBGP peer inside the VPN. The AS path length remains the same, but the values change. XRv1 will iterate over the AS path and make this adjustment before advertising the routes, "overriding" the VPN AS with the SP AS, hence the feature's name. We also don't have to disable the outbound loop-check on XRv1 since the AS override operation happens before the outbound route loop-check/advertisements. After configuring the feature, we can verify the configuration worked by checking the neighbor details.

```
! XRv1
router bgp 214
 vrf BGP
  neighbor 192.11.104.13
    address-family ipv4 unicast
      as-override
    address-family ipv6 unicast
      as-override
```

```
RP/0/0/CPU0:XRv1# show bgp vrf BGP ipv4 unicast neighbors 192.11.104.13 |
utility egrep 'For Address|override'
For Address Family: IPv4 Unicast
  AS override is set
For Address Family: IPv6 Unicast
  AS override is set
```

Next, we can verify that XRv1 is advertising these BGP VPN routes to the CE, which it is. This output does not account for the AS override operation and shows the original VPN AS.

```
RP/0/0/CPU0:XRv1#show bgp vrf BGP ipv4 unicast neighbors 192.11.104.13
advertised-routes
```

Network	Next Hop	From	AS Path
Route Distinguisher: 214:104 (default for vrf BGP)			
192.3.104.0/24	192.11.104.11	214.0.0.3	214 104?
192.4.104.0/24	192.11.104.11	214.0.0.3	214 104?
192.6.104.0/24	192.11.104.11	214.0.0.3	214 104?

192.104.14.14/32	192.11.104.11	214.0.0.3	214 104?

```
RP/0/0/CPU0:XRv1#show bgp vrf BGP ipv6 unicast neighbors 192.11.104.13
advertised-routes
Network                Next Hop          From          AS Path
Route Distinguisher: 214:104 (default for vrf BGP)
::192:104:5:5/128    fd00:192:11:104::11
                        214.0.0.12      214 104?
::192:104:6:6/128    fd00:192:11:104::11
                        214.0.0.3       214 104?
::192:104:14:14/128
                        fd00:192:11:104::11
                        214.0.0.3     214 104?

[snip]
```

Last, we verify that the CE receives the routes without seeing its own AS. The originating AS appears to be 214 according to the new AS path. This scales much better than “allowas-in” because remote CEs can use AS path prepending without necessitating any changes on the local CE.

```
RP/0/0/CPU0:XRv3#show bgp vrf BGP ipv4 unicast neighbors 192.11.104.11 routes

[snip]
```

Now, CSR5 and XRv13 have reachability over the SP network to one another, but CSR6 and XRv14 will have the same problems.

```
R5#ping vrf BGP 192.104.13.13 source 192.104.5.5
Type escape sequence to abort.
Sending 5, 100-byte ICMP Echos to 192.104.13.13, timeout is 2 seconds:
```

Packet sent with a source address of 192.104.5.5

!!!!

Success rate is 100 percent (5/5), round-trip min/avg/max = 5/5/6 ms

For variety, we will troubleshoot XRv4 as if we don't understand the problem. XRv4 only sees its local routes. Debugging BGP updates inbound, we see similar messages as CSR5 whereby the routes advertised by the PE are rejected due to the AS-path. It is interesting to note that XE makes no attempt to filter the routes outbound despite being able to see the loop; we had to disable this intelligent behavior on XRv2.

```
RP/0/0/CPU0:XRv4#show bgp vrf BGP ipv4 unicast | begin Network
```

Network	Next Hop	Metric	LocPrf	Weight	Path
Route Distinguisher: 214:104 (default for vrf BGP)					
*> 192.3.104.0/24	0.0.0.0	0		32768	?
*> 192.6.104.0/24	0.0.0.0	0		32768	?
*> 192.104.14.14/32	0.0.0.0	0		32768	?

```
! XRv4
```

```
bgp[1052]: [default-rtr] VRF BGP (ip4u): UPDATE from 192.3.104.3, prefix  
192.11.104.0/24 (path ID: none) DENIED due to:
```

```
bgp[1052]: [default-rtr] VRF BGP (ip4u): as-path contains our own AS, or 0;
```

We already know there are two solutions: allow AS 104 in on the CE (allowas-in), or change 104 to 214 outbound on the PE (as-override). We will use "allowas-in" to see how it works on XR. As always, after configuring the feature we will verify it was applied to the neighbor properly.

```
! XRv14
```

```
router bgp 104  
vrf BGP  
neighbor 192.3.104.3  
address-family ipv4 unicast  
allowas-in 1  
neighbor fd00:192:3:104::3  
address-family ipv6 unicast  
allowas-in 1
```

```
RP/0/0/CPU0:XRv4#show bgp vrf BGP ipv4 unicast neighbors 192.3.104.3 |

[snip]
```

A quick ping check to CSR5 and XRv13, using a mix of IPv4 and IPv6, shows that XRv14 now has connectivity over the VPN.

```
RP/0/0/CPU0:XRv4#ping vrf BGP 192.104.5.5 source 192.104.14.14
Type escape sequence to abort.
Sending 5, 100-byte ICMP Echos to 192.104.5.5, timeout is 2 seconds:
!!!!!!
Success rate is 100 percent (5/5), round-trip min/avg/max = 1/7/9 ms

RP/0/0/CPU0:XRv4#ping vrf BGP ::192:104:13:13 source ::192:104:14:14
Type escape sequence to abort.
Sending 5, 100-byte ICMP Echos to ::192:104:13:13, timeout is 2 seconds:
!!!!!!
Success rate is 100 percent (5/5), round-trip min/avg/max = 1/6/9 ms
```

Last, we need to fix CSR6. We have already seen the problem several times so we will fix it quickly by enabling AS override on CSR4. After configuring, we verify that it was applied to the VPN peer.

! CSR6

```
router bgp 214
 address-family ipv4 vrf BGP
   neighbor 192.4.104.6 as-override
 address-family ipv6 vrf BGP
   neighbor FD00:192:4:104::6 as-override
```

```
R4#show bgp vpnv4 unicast vrf BGP neighbors 192.4.104.6 | include For
address|Override
```

```
For address family: VPNv4 Unicast
Overrides the neighbor AS with my AS before sending updates
```

```
R4#show bgp vpnv6 unicast vrf BGP neighbors FD00:192:4:104::6 | include For
address|Override
```

```
For address family: VPNv6 Unicast
Overrides the neighbor AS with my AS before sending updates
```

CSR6 receives the IPv4 and IPv6 routes. For variety, we will check the specific IPv4 route to XRv4 and IPv6 route to CSR5. Notice that the AS path is “214 214” as expected per the AS override feature.

```
R6#show bgp vpnv4 unicast vrf BGP 192.104.13.13/32

SoO works similarly in BGP as it does in EIGRP. Since we are bending the eBGP loop-prevention rules, there are cases where AS 104 routes don't have AS 104 in the AS path, and may bounce around inside AS 104 freely. They may even become best-paths, which can cause suboptimal traffic patterns or loops. The simplest SoO deployment is having the PEs identify the PEs are being in the same site. For example, assuming CSR5 and XRv4 were located together, there may never be a case where traffic between these routers should transit the WAN. To implement this, we can configure XRv2 and XRv1 to identify a

common SoO for this site and apply it to the CE routers. We can apply it directly to a neighbor under a specific AFI or use an RPL for additional granularity (per-prefix matches, etc). I demonstrate both methods below.

```
! XRv1
router bgp 214
  vrf BGP
    neighbor 192.11.104.13
      remote-as 104
      address-family ipv4 unicast
        site-of-origin 214:513

! XRv2
route-policy RPL_FROM_CSR5
  set extcommunity soo (214:513)
end-policy

router bgp 214
  vrf BGP
    neighbor 192.12.104.5
      remote-as 104
      address-family ipv4 unicast
        route-policy RPL_FROM_CSR5 in
```

After applying these configurations and refreshing the BGP routes, we notice that the MPLS network cannot be used for transit between CSR5 and XRv3 anymore. This would be ideal for multi-homed scenarios where east-west traffic should be LAN-based (backdoor link only), even in failure cases. A quick check shows that the two routers are exchanging loopbacks via iBGP, which are both best-paths.

```
R5#show bgp vpnv4 unicast vrf BGP 192.104.13.13/32
BGP routing table entry for 214:104:192.104.13.13/32, version 10

      Origin incomplete, metric 0, localpref 100, valid, internal, best,
      rx pathid: 0, tx pathid: 0x0

RP/0/0/CPU0:XRv3#show bgp vpnv4 unicast vrf BGP 192.104.5.5/32 | begin Local$
  Local
    192.5.104.5 from 192.5.104.5 (5.5.5.5)
      Origin incomplete, metric 0, localpref 100, valid, internal, best,
      group-best, import-candidate
      Received Path ID 0, Local Path ID 1, version 118
```

As a PE, XRv2 sees both paths, each of which originates from AS 104. Looking at XRv3's loopback, it is received from XRv1 (iBGP over MPLS) and from CSR5 (eBGP from customer). Hot-potato routing shows that the eBGP path is preferred as best, so XRv2 will not advertise the route from XRv3 any further.

```

      Extended community: SoO:214:513 RT:214:104
      Source VRF: BGP, Source Route Distinguisher: 214:104
```

As a side note, it isn't a good idea to make a PE the RR. Because XRv2 has selected the path through CSR5 as best, other nodes will route through CSR5 to reach XRv3 when transiting XRv1 would have been better. This may cause suboptimal routing depending on the bandwidth of the links, administrative policies, etc. SoO does not aim to fix this specifically.

```
R6#traceroute vrf BGP 192.104.13.13 source 192.104.6.6
Type escape sequence to abort.

```

We will continue testing BGP with SoO. If we break the BGP connection between CSR5 and XRv3, the two routers will no longer be able to communicate. Now, XRv2 selects XRv1 as the best-path to XRv3's

loopback, but should not advertise it to CSR5 due to SoO restrictions. However, XRv2 still is advertising it to CSR5 despite SoO. This appears incorrect.

```

```

A similar check on XRv1 yields better results. XRv1 does not advertise CSR5's loopback to XRv3, as expected. Two-way connectivity is therefore broken, but CSR5 should not have received the routes from XRv2 in the first place.

```

192.104.14.14/32        192.11.104.11          214.0.0.3           214 104?
```

The issue with using an RPL to set SoO on ingress is that the automatic filtering that SoO provides is then lost. We would need to manually match the SoO in an outbound RPL for that peer to drop the routes. This is a design consideration of SoO by making it more configuration intensive at the cost of having additional granularity. On XRv1, specifying a neighbor-level SoO automatically works bidirectionally, so XRv1's configuration is complete.

```
! XRv2
route-policy RPL_TO_CSR5
  if extcommunity soo matches-every (214:513) then
    drop
  else
    pass
  endif
end-policy

router bgp 214
vrf BGP
  address-family ipv4 unicast
  neighbor 192.12.104.5
  address-family ipv4 unicast
  route-policy RPL_TO_CSR5 out
```

After applying this new policy, XRv2 cannot advertise XRv3's loopback to CSR5. Neither CSR5 nor XRv3 have routes to one another's loopback, which is expected when the backdoor is down.

```
RP/0/0/CPU0:XRv2#show bgp vrf BGP ipv4 unicast neighbors 192.12.104.5
advertised-routes
Network                Next Hop                From                AS Path

```

Notice that IPv6 connectivity is totally unaffected when the backdoor is down. SoO is enabled per AFI, unlike EIGRP, so we can have different “site-based” topologies for IPv4 and IPv6. Both CSR5 and XRv3 have IPv6 routes towards one another’s loopbacks.

```
R5#show bgp vpnv6 unicast vrf BGP ::192:104:13:13/128

```

We can also use an approach similar to that tested in the EIGRP section, whereby a site “guards” itself with the same SoO around the perimeter routers to prevent routes from that site entering again, be it via the SP network or backdoor links. On the left side of the network, we will first begin by enabling SoO on the PE devices. CSR6 and XRv4 will be considered in different “sites” so that they can talk over MPLS or the backdoor. We will use the per-neighbor method on CSR3 and the route-map method on CSR4. We also advertise the PE-CE link into BGP so we can test the feature as we did for EIGRP.

```
! CSR3
router bgp 214
  address-family ipv4 vrf BGP
    network 192.3.104.0
    neighbor 192.3.104.14 soo 214:3
  address-family ipv6 vrf BGP
    network FD00:192:3:104::/64
    neighbor FD00:192:3:104::14 soo 214:3
```

```

! CSR4
route-map RM_SOO_IN permit 10
  set extcommunity soo 214:4

address-family ipv4 vrf BGP
  network 192.4.104.0
  neighbor 192.4.104.6 route-map RM_SOO_IN in
address-family ipv6 vrf BGP
  network FD00:192:4:104::/64
  neighbor FD00:192:4:104::6 route-map RM_SOO_IN in

```

Unlike XR, which has no command to verify per-neighbor SoO, XE will show this under the neighbor details. As expected, when using the route-map, it will not.

```

R3#show bgp vpnv4 unicast vrf BGP neighbors 192.3.104.14 | include v4|Origin
  Address family IPv4 Unicast: advertised and received
  For address family: VPNv4 Unicast
  Translates address family IPv4 Unicast for VRF BGP
  neighbor Site-of-Origin is SoO:214:3

```

```

R3#show bgp vpnv6 unicast vrf BGP neighbors fd00:192:3:104::14 | include
v6|Origin
  Address family IPv6 Unicast: advertised and received
  For address family: VPNv6 Unicast
  Translates address family IPv6 Unicast for VRF BGP
  neighbor Site-of-Origin is SoO:214:3

```

Looking at CSR3's view of the connected PE-CE link between itself and XRv4, we can see both SoO impositions are not quite working. The remotely learned route from the eBGP peer (XRv4) has the proper SoO applied, but the connected route via the network statement does not. Unlike EIGRP, SoO is being applied to routes learned from a peer, not routes recursing out of a given interface. BGP has no concept of interfaces.

```

Applying a route-map to the BGP network statement does not work, although one would think that it would manually adjust the attributes of the prefix. Instead, we can use the interface-level command that is protocol-agnostic to solve this problem. For a quick side-demo, we will set a bogus SoO just to see if it accidentally overrides the BGP-level neighbor one for routes learned via that interface. Fortunately, it does not. We know we will have the exact same problem on CSR4, so we will correct the problem there also.

```

! CSR3 and CSR4
route-map RM_SOO_IN permit 10
  set extcommunity soo 214:999

Extended Community: SoO:214:3 RT:214:104
```

Since we know the locally-originated route is the best-path, CSR3 can advertise this to CSR4. It carries the SoO attribute. CSR4 learns 3 routes; one directly from CSR3 (RR), another reflected from XRv2 (RR), and one from the eBGP peer CSR6. The best-path is the one from CSR3 since the peer ID 214.0.0.3 is less than 214.0.0.12 (worst tiebreaker). This is because the BGP RID of 214.0.0.3 is compared against the originator ID of the same value from XRv2, which results in a tie. The AS path length is 0 which immediately disqualifies the eBGP path.

```

CSR4 then advertises this to CSR6, who should ideally see SoO:214:3. CSR6 doesn't see any SoO information on the route received from CSR4. Recall that XE does not send communities by default, and XR does not send communities to eBGP neighbors by default.

```
R6#show bgp vpnv6 unicast vrf BGP fd00:192:3:104::/64

```

We will quickly enable the sending of extended communities to eBGP peers on CSR3 and CSR4.

```

! CSR3
router bgp 214
  address-family ipv6 vrf BGP
    neighbor FD00:192:3:104::14 send-community extended

! CSR4
router bgp 214
  address-family ipv6 vrf BGP
    neighbor FD00:192:4:104::6 send-community extended

```

Now, we can see the SoO on CSR6 as expected. We also check the PE-CE link between CSR4/CSR6 on XRv4; it can see SoO:214:4 as imposed by CSR4. These connected-route impositions required the interface-level site-map command since the BGP-level SoO configuration does not affect locally-originated routes.

```

```

Because those connected routes were technically originated in AS 214, the AS path check will pass without needing “allowas-in” or “as-override”. Shutting down CSR6’s PE-CE link proves that CSR6 can still learn that connected route with SoO:214:4 from XRv4. Normally, this is the situation we are trying to prevent, since CSR4 is effectively learning a route from its local “site”.

```

R6#show bgp vpnv6 unicast vrf BGP fd00:192:4:104::/64
BGP routing table entry for [214:104]FD00:192:4:104::/64, version 1656

  Refresh Epoch 1
  214
    FD00:192:6:104::14 (via vrf BGP) from FD00:192:6:104::14 (14.14.14.14)
      Origin IGP, localpref 100, valid, internal, best
      Extended Community: SoO:214:4
      rx pathid: 0, tx pathid: 0x0

```

Next, we need to configure the SoO on the backdoor peerings for IPv6 at a minimum, as well as ensure extended-communities are being exchanged more liberally since SoO is being actively used by PE and CE routers. CSR6 will identify as being in site 4 while XRv4 will be in site 3. XR automatically sends communities inside of iBGP, so it only needs to be explicitly enabled with the eBGP PE.

```

! XRv4
router bgp 214
  vrf BGP
    neighbor fd00:192:3:104::3

```

```

    remote-as 214
    address-family ipv6 unicast
        send-extended-community-ebgp
neighbor fd00:192:6:104::6
    remote-as 104
    address-family ipv6 unicast
        site-of-origin 214:3

! CSR6
router bgp 104
    address-family ipv6 vrf BGP
        neighbor FD00:192:4:104::4 send-community extended
        neighbor FD00:192:6:104::14 send-community extended
        neighbor FD00:192:6:104::14 soo 214:4

```

XR doesn't allow this to be committed and claims the SoO is an eBGP-only configuration. However, XE takes the code, so we will attempt it. According to this, the third SoO technique is not supported on XR.

```

! XRv4
neighbor fd00:192:6:104::6
    address-family ipv6 unicast
        site-of-origin 214:3
!!% Change would result in internal neighbor (fd00:192:6:104::6 VRF BGP) with
external-only config

```

We verify that the configuration was successful on CSR6. Despite multiple BGP hard resets, CSR6 still learns the route regardless of whether the BGP SoO is set or not. XR warned us that this wasn't supported, but XE seems to accept the configuration and gives no indication of a problem, either in show or debug commands. This suggests that the "perimeter" technique is not supported on either platform and is likely specific to EIGRP deployments.

```

R6#show bgp vpnv6 unicast vrf BGP neighbors FD00:192:6:104::14 | include

        Extended Community: SoO:214:4

```

```
rx pathid: 0, tx pathid: 0x0
```

In summary, it appears that BGP SoO is best used in the strict sense of identifying sites so that intra-site traffic does not transit the SP network. Usage of the site-map command is very rare with BGP and was used for demonstration purposes only, however using it in this way does speak to its flexibility. There is another handy use for SoO which can be used to reduce suboptimal routing. Considering, at present, routes learned via CSR3 have SoO:214:3 and routes via CSR4 have SoO:214:4, we have a “tag” on routes based on which PE they were learned from. When all links in the network are up, CSR4 learns routes behind the remote CE (the one to which it is not connected) via eBGP. This means that traffic routed to CSR4 destined for networks behind XRv4 will transit the (possibly) slow backdoor link. It may be desirable for CSR4 to prefer the iBGP route via CSR3 because that PE-CE link (CSR3/XRv4) is much faster, where CSR4 is just a backup. Following this scenario, we can adjust the best-path selection algorithm based on prefixes to achieve this. Matching on SoO is a simple and dynamic way, especially if it is already being used for loop control in other parts of the network.

```

```

Since the BGP peer over iBGP is VPNv6, and the eBGP peer is IPv6 unicast inside of a VRF, we cannot just apply a route-map to the VPNv6 peer if other VRFs are using the same SoO. For example, if SoO:214:3 is being used by VRF EIGRP, for example, the route-map could have unintended effects. In this case, we are safe, but it is a future consideration. The route-map effectively says “routes from site 3 should be preferred via CSR3”, which is a very logical decision.

```
! CSR4
ip extcommunity-list standard EXTCOML_SOO_3 permit soo 214:3
```

```

route-map RM_BGP_CSR3_IN permit 10
  match extcommunity EXTCOML_SOO_3
  set local-preference 200
route-map RM_BGP_CSR3_IN permit 1000

router bgp 214
  address-family vpnv6
    neighbor 214.0.0.3 route-map RM_BGP_CSR3_IN in

```

After a soft reset, we verify the local preference update was successful. Now CSR4 prefers the path over MPLS; we verify with traceroute.

```

R4#traceroute vrf BGP ipv6 ::192:104:14:14
Type escape sequence to abort.
Tracing the route to ::192:104:14:14
 1 FD00:192:3:104::3 [MPLS: Label 3009 Exp 0] 4 msec 2 msec 3 msec
 2 ::192:104:14:14 [AS 104] 4 msec 4 msec 3 msec

```

The downside of this approach is that now CSR4 will prefer CSR3 for all traffic going into AS 104. Adding some kind of non-overlapping attributes (possibly prefixes, RTs, other custom communities, etc) to the route-map match clauses can add granularity to this routing enhancement. Applying this policy everywhere would make sense, but I demonstrate it only on CSR4 for brevity.

```

```

The reachability script is below. The only failure will be between CSR5 and XRv3 since the backdoor is down and their PEs assert that those routers belong to the same “site”. This was to demonstrate SoO specifically. Bringing it up yields full reachability.

```

! CSR5 and CSR6
tclsh
foreach x {
192.104.5.5
192.104.6.6
192.104.13.13
192.104.14.14
::192:104:5:5
::192:104:6:6
::192:104:13:13
::192:104:14:14
} { ping vrf BGP $x source loopback104 repeat 3 timeout 1 }

```

38.1.6 Static routing

Static routing is another possible way to achieve PE-CE routing. Most service providers will offer either BGP or static routing as options due to their widespread support and simplicity. Looking at CSR4 and XRv2, all we have to do is add a VRF-aware static route and redistribute it into BGP per AFI.

```

! CSR4
ip route vrf STATIC 192.105.6.6 255.255.255.255 Gig2.105 192.4.105.6
ipv6 route vrf STATIC ::192:105:6:6/128 Gig2.105 FD00:192:4:105::6

router bgp 214
 address-family ipv4 vrf STATIC
   redistribute static
 address-family ipv6 vrf STATIC
   redistribute static

```

```

! XRv2
router static
  vrf STATIC
    address-family ipv4 unicast
      192.105.5.5/32 GigabitEthernet0/0/0/0.105 192.12.105.5
    address-family ipv6 unicast
      ::192:105:5:5/128 GigabitEthernet0/0/0/0.105 fd00:192:12:105::5

router bgp 214
  vrf STATIC
    rd 214:105
    address-family ipv4 unicast
      redistribute static
    address-family ipv6 unicast
      redistribute static

```

Using some lesser-known static routing show commands, we can verify the static routes inside of the VRF, per AFI.

```

RP/0/0/CPU0:XRv2#show static vrf STATIC ipv4 unicast topology
VRF: STATIC Table Id: 0xe0000018 AFI: IPv4 SAFI: Unicast
Prefix/Len      Interface      Nexthop      Object      Metrics
192.105.5.5/32  GigabitEthernet0_0_0_0.105 192.12.105.5  None        [0/0/1/0]

RP/0/0/CPU0:XRv2#show static vrf STATIC ipv6 unicast topology
VRF: STATIC Table Id: 0xe0800018 AFI: IPv6 SAFI: Unicast
Prefix/Len      Interface      Nexthop      Object      Metrics
::192:105:5:5/128  GigabitEthernet0_0_0_0.105 fd00:192:12:105::5  None        [0/0/1/0]

R4#show ip static route vrf STATIC
Codes: M - Manual static, A - AAA download, N - IP NAT, D - DHCP,
      [snip]
Codes in []: A - active, N - non-active, B - BFD-tracked, D - Not Tracked, P
- permanent
Static local RIB for STATIC
M 192.105.6.6/32 [1/0] via GigabitEthernet2.105 192.4.105.6 [A]

R4#show ipv6 static vrf STATIC
IPv6 Static routes Table - STATIC
Codes: * - installed in RIB, u/m - Unicast/Multicast only
      [snip]
* ::192:105:6:6/128 via FD00:192:4:105::6, GigabitEthernet2.105, distance 1

```

A quick check on XRv2 shows all of the remote static routes inside of BGP with the proper VPNv4 next hops for both AFIs. Based on this, we can assume all of the static-to-BGP redistribution was successful on all 4 PEs within VRF STATIC.

```

RP/0/0/CPU0:XRv2#show bgp vpnv4 unicast vrf STATIC | begin Network
Network      Next Hop      Metric LocPrf Weight Path

```

```

Route Distinguisher: 214:105 (default for vrf STATIC)
*> 192.105.5.5/32      192.12.105.5          0          32768 ?
*>i192.105.6.6/32     214.0.0.4              0      100      0 ?
*>i192.105.13.13/32   214.0.0.11             0      100      0 ?
*>i192.105.14.14/32   214.0.0.3              0      100      0 ?

RP/0/0/CPU0:XRv2#show bgp vpnv6 unicast vrf STATIC | begin Network
      Network          Next Hop          Metric LocPrf Weight Path
Route Distinguisher: 214:105 (default for vrf STATIC)
*> ::192:105:5:5/128  fd00:192:12:105::5
                                0          32768 ?
*>i::192:105:6:6/128  214.0.0.4              0      100      0 ?
*>i::192:105:13:13/128
                        214.0.0.11             0      100      0 ?
*>i::192:105:14:14/128
                        214.0.0.3              0      100      0 ?

```

We also need to ensure the CE routers have static routes pointing towards the PE. A simple default for IPv4 and IPv6 would work, but we will use a coarse aggregate for variety. Only configurations on XRv3 and CSR5 are shown for brevity. Assuming this MPLS network was also the mechanism by which CEs reached the Internet, a default route is most appropriate. If not, a coarse aggregate encompassing all of the WAN subnets would work well, with a default pointing elsewhere towards the Internet.

```

! CSR6
ip route vrf STATIC 192.0.0.0 255.0.0.0 GigabitEthernet2.105 192.12.105.12
ipv6 route vrf STATIC ::192:0:0:0/80 GigabitEthernet2.105 FD00:192:12:105::12

! XRv3
router static
vrf STATIC
  address-family ipv4 unicast
    192.0.0.0/8 GigabitEthernet0/0/0/0.105 192.11.105.11
  address-family ipv6 unicast
    ::192:0:0:0/80 GigabitEthernet0/0/0/0.105 fd00:192:11:105::11

```

There isn't much more to test at this point, so we will verify reachability before continuing. Running this script from the XE CEs is a quick way to ensure all 4 sites in the STATIC VPN can communicate.

```

! CSR5 and CSR6
tclsh
foreach x {
192.105.5.5
192.105.6.6
192.105.13.13
192.105.14.14
::192:105:5:5
::192:105:6:6

```

```

::192:105:13:13
::192:105:14:14
} { ping vrf STATIC $x source loopback105 repeat 3 timeout 1 }

```

As a quick note, SoO can also apply to static routes provided they point traffic out of the interface to which the SoO is applied. XR does not support this, but XE does. This would only be useful if BGP was used somewhere in the VPN, as it was for IS-IS, which is where the filtering would happen. Even if we use the same SoO on CSR3 and CSR4, CSR6 and XRv4 will still be able to talk to one another. BGP will import the routes into the proper table, but since static routing is used, there is no possible way for the SoO to be “advertised” into the customer domain.

```

! CSR3 and CSR4
route-map RM_STATIC_SOO permit 10
  set extcommunity soo 214:105

interface GigabitEthernet2.105
  ip vrf sitemap RM_STATIC_SOO

```

We verify that SoO:214:105 has been applied by both CSR3 and CSR4 on their locally redistributed static routes. The information is exchanged, but no filtering occurs since there is nothing being advertised to the CE routers, as described above. Without a PE-CE protocol, the SoO could be used as a route-tag as seen in the BGP section for best-path adjustment, but in that case, using ordinary communities would be more appropriate.

```

38.1.7 RIP

RIP is a very uncommon PE-CE option but it is supported in XE and XR. XR does not support RIPng (IPv6) at all, and because of the high density of XR in the network, RIPng is not tested. Below are the PE configurations for RIPv2 on an XE and XR PE. When redistributing from BGP, we can set the metric to transparent which allows RIP to copy the BGP MED value when importing routes from BGP. We won't need this command in XR as it is automatic so long as we don't specify a hard metric.

```
! CSR4
router rip
  address-family ipv4 vrf RIP
    redistribute bgp 214 metric transparent
    network 192.4.106.0
    no auto-summary
    version 2

! XRv2
router rip
  vrf RIP
    interface GigabitEthernet0/0/0/0.106
    redistribute bgp 214
```

The CE configurations are nearly identical, except there is no BGP redistribution and RIP is enabled on the loopbacks/backdoors. The backdoors are currently shutdown.

```
! CSR6
router rip
  address-family ipv4 vrf RIP
    network 192.4.106.0
    network 192.6.106.0
    network 192.106.6.0
    no auto-summary
    version 2

! XRv3
router rip
  vrf RIP
```

```

interface Loopback106
  passive-interface
interface GigabitEthernet0/0/0/0.106
interface GigabitEthernet0/0/0/0.206

```

Checking XRv2, we can see all of the RIP loopbacks in BGP VPNv4, which means the RIP advertisement from CE to PE, and the redistribution from RIP, were successful. All of the PE-CE transit links are included by default as well.

```

RP/0/0/CPU0:XRv2#show bgp vpnv4 unicast vrf RIP | begin Network
  Network                Next Hop                Metric LocPrf Weight Path
Route Distinguisher: 214:106 (default for vrf RIP)
*>i192.3.106.0/24        214.0.0.3                0      100      0 ?
*>i192.4.106.0/24        214.0.0.4                0      100      0 ?
*>i192.11.106.0/24       214.0.0.11               0      100      0 ?
*> 192.12.106.0/24       0.0.0.0                  0              32768 ?
*> 192.106.5.5/32        192.12.106.5             1              32768 ?
*>i192.106.6.6/32        214.0.0.4                1      100      0 ?
*>i192.106.13.13/32      214.0.0.11               1      100      0 ?
*>i192.106.14.14/32      214.0.0.3                1      100      0 ?

```

Although unrelated to RIP, we will perform some cleanup by removing all of these connected routes. This is a good practice for EIGRP and OSPF also. Doing so is simple; a deny-all route-map/RPL applied to connected redistribution will take explicit control of the connected routes and deny them. Only true RIP-learned routes will be permitted since that redistribution is unfiltered. This solution scales better than a “white-list” prefix-filter under RIP since any RIP-learned prefix is now allowed by default.

```

! CSR3 and CSR4
route-map RM_DENY_ALL deny 10

router bgp 214
  address-family ipv4 vrf RIP
    redistribute connected route-map RM_DENY_ALL
    redistribute rip

! XRv1 and XRv2
route-policy RPL_DENY_ALL
  drop
end-policy

router bgp 214
  vrf RIP
    address-family ipv4 unicast
      redistribute connected route-policy RPL_DENY_ALL
      redistribute rip

```

Checking XRv2 again, all we see are the loopbacks without the PE-CE transit links, as expected.

```

RP/0/0/CPU0:XRv2#show bgp vpnv4 unicast vrf RIP | begin Network
  Network                Next Hop                Metric LocPrf Weight Path
Route Distinguisher: 214:106 (default for vrf RIP)
*> 192.106.5.5/32        192.12.106.5                1              32768 ?
*>i192.106.6.6/32        214.0.0.4                  1      100        0 ?
*>i192.106.13.13/32     214.0.0.11                 1      100        0 ?
*>i192.106.14.14/32     214.0.0.3                  1      100        0 ?

```

For additional complexity, we will open backdoor connections between XRv4/CSR6 and CSR5/XRv3. Because RIP is hop-count based, the CEs will prefer this backdoor over the MPLS network. Also note that our fancy “redistribute connected” filter is no longer effective since transit links can be learned via RIP now; we will ignore this as it is outside the scope of this test (we could easily filter it from RIP updates). We will pretend that CSR6 and XRv4 actually are in the same site and should never reach one another via MPLS. SoO seems like it might work here, so we will test it. We will re-use some old route-maps that have the same SoO from older testing.

```

! CSR3 and CSR4
interface GigabitEthernet2.106
 ip vrf sitemap RM_STATIC_SO

```

Checking CSR3, it has a locally-originated route (redistributed from RIP) and an iBGP learned one from CSR4. As expected, both of them have the same SoO.

```

R3#show bgp vpnv4 unicast vrf RIP 192.106.14.14/32

```

To speed up the convergence process, we can shut down the backdoor link on both CSR6 and XRv4 concurrently. SoO actually does work for RIP filtering; CSR6 and XRv4 do not have routes for one another's loopback anymore, despite the PEs having the routes in their local VPN tables. Debugging RIP on CSR3, we do not see CSR6's loopback being advertised to XRv4 at all. CSR3 did properly redistribute this route from BGP into RIP, as the database shows.

```
R3#show ip rip database vrf RIP 192.106.6.6 255.255.255.255
192.106.6.6/32      redistributed
    [2] via 214.0.0.4,
```

```
! CSR3
RIP: sending v2 update to 224.0.0.9 via GigabitEthernet2.106 (192.3.106.3)
RIP: build update entries
    192.5.106.0/24 via 0.0.0.0, metric 2, tag 0
    192.11.106.0/24 via 0.0.0.0, metric 3, tag 0
    192.12.106.0/24 via 0.0.0.0, metric 3, tag 0
    192.106.5.5/32 via 0.0.0.0, metric 2, tag 0
    192.106.13.13/32 via 0.0.0.0, metric 2, tag 0
```

```
RP/0/0/CPU0:XRv4#show route vrf RIP 192.106.6.6
% Network not in table
```

CSR5 and XRv3 will be in “different” sites but should prefer MPLS over the backdoor. We can use an offset list on the CE router backdoor interfaces to make this link less preferable. For example, CSR5 is currently preferring the backdoor link to reach XRv3's loopback.

```
R5#show ip route vrf RIP 192.106.13.13
Routing Table: RIP
Routing entry for 192.106.13.13/32
    Known via "rip", distance 120, metric 1
    Redistributing via rip
    Last update from 192.5.106.13 on GigabitEthernet2.206, 00:00:19 ago
    Routing Descriptor Blocks:
    * 192.5.106.13, from 192.5.106.13, 00:00:19 ago, via GigabitEthernet2.206
        Route metric is 1, traffic share count is 1
```

I am surprised to see that XR even has a site-of-origin command for RIP. We will use another traditional multi-site SoO design on these routers where each PE router has a different SoO. This means that a routing update loop will stop at the originating PE if the route manages to come “full circle”, but this assumes RIP can somehow carry SoO (which it does not appear to). There is no backdoor filtering. This design would be more relevant for EIGRP than anything else since EIGRP can carry SoO.

```
! CSR5
router rip
    address-family ipv4 vrf RIP
        offset-list 0 in 8 GigabitEthernet2.206
```

```

! XRv3
route-policy RPL_ADD_8
  add rip-metric 8
end-policy

router rip
vrf RIP
  interface GigabitEthernet0/0/0/0.206
    route-policy RPL_ADD_8 in

```

On the PEs, we need to configure the SoO on the PE-CE link as well. This completes the SoO design.

```

! XRv1
router rip
vrf RIP
  interface GigabitEthernet0/0/0/0.106
    site-of-origin 214:9013

! XRv2
router rip
vrf RIP
  interface GigabitEthernet0/0/0/0.106
    site-of-origin 214:9005

```

Verifying some BGP routes on XRv2, we can see the loopback CSR5 with SoO values of 214:9013 and 214:9005, respectively. One was locally originated and one was iBGP-learned. These values were imposed by the PEs at the redistribution point.

```

RP/0/0/CPU0:XRv2#show bgp vpnv4 unicast vrf RIP 192.106.5.5/32 | begin Local$

```

There is a race condition regarding XRv2's view of XRv3's loopback. If it learns the RIP route from CSR5 first, it will install it into the RIB and advertise it into BGP. We can simulate this by shutting down the

BGP peering to XRv1 for a minute or so. In this case, XRv2 routes the traffic to CSR5 and then over the backdoor. This implies that CSR5's route is via the slow back door, which is not what we want.

```

    Route metric is 9, traffic share count is 1
```

If XRv2 learns the BGP route first, it will install it in the RIB, advertise it to CSR5 with a low metric, and CSR5 will install it. We can simulate this by breaking the backdoor link on CSR5's side for a minute or so. This is a more ideal end-state since the customer is using MPLS over the slow backdoor.

```
RP/0/0/CPU0:XRv2#show bgp vpnv4 unicast vrf RIP 192.106.13.13/32 | begin

R5#show ip route vrf RIP 192.106.13.13
```

Routing Table: RIP

Routing entry for 192.106.13.13/32

Known via "rip", distance 120, metric 2

Redistributing via rip

Last update from 192.12.106.12 on GigabitEthernet2.106, 00:00:25 ago

Routing Descriptor Blocks:

* 192.12.106.12, from 192.12.106.12, 00:00:25 ago, via GigabitEthernet2.106

Route metric is 2, traffic share count is 1

Solutions to prevent this situation are numerous: metric based ingress filtering on the PEs or egress filtering on the CEs to prevent remote routes from even hitting the MPLS network would be best. Unfortunately, we can't use the RPL to match RIP metrics, otherwise this would be a clean solution. We can match prefixes directly and filter them, which scales poorly but is effective. We will use ingress filtering on XRv1 and XRv2 to ensure routes that came over the backdoor (we can tell by the huge metric) cannot be installed in the routing table. The downside of this approach is that if a PE-CE link fails, the PE "diagonal" from a CE will not have reachability, which is a rare case. We use opposing logic in the RPLs for variety.

```
! XRv1
route-policy RPL_RIP_FILTER
  if not destination in (192.106.13.13/32) then
    drop
  else
    pass
  endif
end-policy
```

```
! XRv2
route-policy RPL_RIP_FILTER
  if destination in (192.106.13.13/32) then
    pass
  else
    drop
  endif
end-policy
```

```
! XRv1 and XRv2
router rip
vrf RIP
interface GigabitEthernet0/0/0/0.106
  route-policy RPL_RIP_FILTER in
```

To test it, we can break the BGP connection between XRv1 and XRv2 again. The CE routers will utilize the slow backdoor to communicate and advertise one another's loopbacks to the PEs. The PEs should reject it, ultimately having no routes to the diagonally-opposed CEs. Only the local loopbacks are allowed.

```
RP/0/0/CPU0:XRv1#show route vrf RIP rip
```

```
R 192.106.13.13/32 [120/1] via 192.11.106.13, 02:49:50,  
GigabitEthernet0/0/0/0.106
```

```
RP/0/0/CPU0:XRv2#show route vrf RIP rip
```

```
R 192.106.5.5/32 [120/1] via 192.12.106.5, 00:01:27,  
GigabitEthernet0/0/0/0.106
```

The backdoor link continues to work as an alternate path when the MPLS network fails.

```
R5#ping vrf RIP 192.106.13.13 source 192.106.5.5  
Type escape sequence to abort.  
Sending 5, 100-byte ICMP Echos to 192.106.13.13, timeout is 2 seconds:  
Packet sent with a source address of 192.106.5.5  
!!!!!  
Success rate is 100 percent (5/5), round-trip min/avg/max = 2/3/4 ms
```

When BGP comes back online, both PEs only see the BGP learned router, ensuring that the PEs immediately prefer the MPLS network again without question.

```
R5#show ip cef vrf RIP 192.106.13.13  
192.106.13.13/32  
  nexthop 192.12.106.12 GigabitEthernet2.106
```

```
RP/0/0/CPU0:XRv3#show cef vrf RIP ipv4 192.106.5.5/32  
192.106.5.5/32, version 105, internal 0x1000001 0x0 (ptr 0xa144ad74) [1], 0x0  
(0xa142e250), 0x0 (0x0)  
local adjacency 192.11.106.11  
  Prefix Len 32, traffic index 0, precedence n/a, priority 2  
  via 192.11.106.11, GigabitEthernet0/0/0/0.106, 5 dependencies, weight 0,  
class 0 [flags 0x0]  
  path-idx 0 NHID 0x0 [0xa0ec734c 0x0]  
  next hop 192.11.106.11  
  local adjacency
```

Finally, we test connectivity between all sites. CSR6 and XRv4 cannot communicate only because the backdoor is down (PE imposes the same SoO), but otherwise, there is full reachability.

```
! CSR5 and CSR6  
tclsh  
foreach x {  
192.106.5.5  
192.106.6.6  
192.106.13.13  
192.106.14.14  
} { ping vrf RIP $x source loopback106 repeat 3 timeout 1 }
```

38.2 VRF label modes

When using VPNv4/v6 BGP to allocate labels for VPN prefixes, we are often accustomed to seeing a unique VPN label per customer prefix. The logic is that this label serves as a demultiplexer value; when the label is received from the MPLS core, the egress LSR performs a single LFIB lookup on a single label in a single table. There is no need to look at the IPv4/v6 destination since the local label that was allocated will determine the IPv4/v6 next-hop within the VPN, as well as represent a specific customer prefix. This is an intelligent approach, but comes with scalability limitations. The most obvious example is transporting the Internet prefixes inside of a central-service L3VPN. Allocating ~350,000 labels is more than one third of the available MPLS label space, not to mention increased burden on the router in terms of memory (large LIB, LFIB, etc). New options were invented to help increase efficiency with respect to label resource management.

The first and oldest alternative was to allocate labels on a per-VRF basis. For each customer, there will be a single, common VPN label allocated by BGP for VPNv4/v6. The drawback of this approach is that it violates one of the original designs of MPLS. When the aggregate VPN label arrives on an egress PE from the core, it could represent any prefix within a given VPN, so the router must perform a second FIB (not LFIB) lookup on the IPv4/v6 destination address to determine how to route it. In cases where there is only a single PE-CE link per VPN, this is obviously inefficient/unnecessary and could affect performance. When there are multiple PE-CE links in the same VPN, the inefficiency remains but it is necessary since the next-hop CE may vary depending on the VPN prefix. Below is the original output of the BGP allocated labels without modification. We see a unique VPN label for each prefix, which is the default.

```
R7#show bgp vpnv4 unicast vrf TOP labels | include 88\.

[snip]
```

We have the flexibility to change this per protocol (VPNv4 or VPNv6) or for all protocols, as well as per VRF or for all VRFs. We will enable it on CSR7 inside VRF TOP for VPNv4 only. Notice that CSR7 learns several 88.0.0.0/8 routes from CSR10, and advertises a local loopback inside the same VRF. Before issuing the command, each one had a different label as shown above. Afterwards, however, they all use the same label, regardless of the route's origination. The label is explicitly marked as an IPv4 VRF aggregate label for clarity.

```
! CSR7
mpls label mode vrf TOP protocol bgp-vpnv4 per-vrf
```

```
R7#show bgp vpnv4 unicast vrf TOP labels | include 88\.
 88.7.7.7/32      0.0.0.0      IPv4 VRF Aggr:7005/nolabel(TOP)
 88.125.160.0/28  10.7.10.10   IPv4 VRF Aggr:7005/nolabel
 88.125.160.16/28 10.7.10.10   IPv4 VRF Aggr:7005/nolabel
```

```

88.125.160.32/28 10.7.10.10 IPv4 VRF Aggr:7005/nolabel
88.125.160.48/28 10.7.10.10 IPv4 VRF Aggr:7005/nolabel
88.125.160.64/27 10.7.10.10 IPv4 VRF Aggr:7005/nolabel
[snip]

```

As a result, packets arriving for 88.7.7.7/32 and 88.125.160.0/28 must be looked up in the LFIB first. The LFIB basically says “this belongs to VRF TOP, but since it is an aggregate label, we don’t know how to forward the packet”. The label is popped to reveal the IPv4 packet. The LFIB entry contains no outgoing interface or next-hop. All it knows is that the IPv4 VRF TOP FIB must be consulted.

```

R7#show mpls forwarding-table labels 7005 detail
Local      Outgoing  Prefix      Bytes Label  Outgoing  Next Hop
Label      Label     or Tunnel Id Switched     interface
7005       Pop Label IPv4 VRF[V]  0            aggregate/ TOP
          MAC/Encaps=0/0, MRU=0, Label Stack{}
          VPN route: TOP
          No output feature configured

```

The second VRF-aware FIB lookup tells us how to route the packet once the MPLS labels are removed. There is no way to carry this information inside of MPLS anymore. As an example, two packets could arrive with identical labels but were forwarded two different ways based on their IPv4 destinations.

```

88.7.7.7/32
receive for Loopback7

R7#show ip cef vrf TOP 88.125.160.0
88.125.160.0/28
nexthop 10.7.10.10 GigabitEthernet2.570

```

The per-VRF label feature was a good “first attempt” at solving this problem. A better approach is to allocate labels per-next-hop, or as Cisco calls it, “per-CE”. Imagine the scenario described earlier with two CEs in the same VRF. We don’t necessarily need an aggregate label for the whole VRF, as this causes inefficiencies in the forwarding lookups. One label per next-hop means that the label can still demultiplex the traffic’s direction, saving the PE an IPv4/v6 FIB lookup. The CE can look at the IP packet and route the traffic as it normally would. This will also work well in our current situation of having a local loopback in the same VRF as customer routes. We can test this using VPNv6; below is the output before any configuration changes where labels are allocated per-prefix by default.

```

R7#show bgp vpnv6 unicast vrf TOP labels | section 2BAD:88
2BAD:88:125:160::/72
                        FD00:10:7:10::10
                        7007/nolabel
2BAD:88:125:160:100::/72
                        FD00:10:7:10::10

```

```

                                7009/nolabel
2BAD:88:125:160:200::/72
                                FD00:10:7:10::10
                                7010/nolabel
2BAD:88:125:160:300::/72
                                FD00:10:7:10::10
                                7011/nolabel

```

Specifically for this VRF (we only have one, so this doesn't matter for CSR7) we will enable the per-CE label allocation. Notice that these labels are not considered "aggregates"; they still have forwarding instructions, as the LFIB will show later. We can see that the next-hop of CSR10 uses label 7020 for all prefixes, while prefixes with next-hop :: (local) use label 7012. Local/aggregate routes would normally share the same label since an IPv4/v6 FIB lookup is required no matter what.

```

! CSR7
mpls label mode vrf TOP protocol bgp-vpnv6 per-ce

R7#show bgp vpnv6 unicast vrf TOP labels | section 2BAD::?88
2BAD::88:7:7/128 :: 7012/nolabel (TOP)
2BAD:88:125:160::/72
                                FD00:10:7:10::10
                                7020/nolabel
2BAD:88:125:160:100::/72
                                FD00:10:7:10::10
                                7020/nolabel
2BAD:88:125:160:200::/72
                                FD00:10:7:10::10
                                7020/nolabel
2BAD:88:125:160:300::/72
                                FD00:10:7:10::10
                                7020/nolabel

```

The LFIB outputs are different for per-CE versus per-VRF. The first entry for label 7020 is an ordinary LFIB entry for a PE router with the exception of the "prefix" field. A "next-hop-ID" is assigned, which we know is CSR10, and is mapped to this specific local label. I cannot find a command to show the next-hop bindings and the relevance of the ID number 3, and Cisco does not discuss it in their documentation. It is not terribly important; the LFIB entry clearly shows CSR10 as the next-hop anyway.

```

R7#show mpls forwarding-table labels 7020 detail
Local      Outgoing   Prefix          Bytes Label  Outgoing   Next Hop
Label      Label      or Tunnel Id    Switched     interface
7020       No Label   nh-id(3)        0            Gi2.570    FE80::10
MAC/Encaps=18/18, MRU=1504, Label Stack{}
005056A9F961005056A9EA7781000DF286DD
No output feature configured

```

Below is the normal L3VPN output for a local/aggregate route. The prefix ID for the loopback prefix is known since the next-hop is local and removing the VPN label is required anyway.

```
R7#show mpls forwarding-table labels 7012 detail
Local      Outgoing  Prefix      Bytes Label  Outgoing  Next Hop
Label      Label      or Tunnel Id Switched      interface
7012       Pop Label  2BAD::88:7:7/128[V]  \
                                         0          aggregate/TOP
      MAC/Encaps=0/0, MRU=0, Label Stack{}
      VPN route: TOP
      No output feature configured
```

All of these label mode modifications can be viewed by checking the VRF details as well. The per-VRF option even shows the label value since it is authoritative for the entire VRF.

```
R7#show vrf detail TOP | include ^Address|label_alloc
Address family ipv4 unicast (Table ID = 0x1):
  VRF label allocation mode: per-vrf (Label 7005)
Address family ipv6 unicast (Table ID = 0x1E000001):
  VRF label allocation mode: per-ce
Address family ipv4 multicast not active
```

We know that the per-CE feature allocates labels per next-hop. We can check the BGP next-hops to see how many are in VRF TOP, which is a good indication of how many labels we need. This doesn't account for local/aggregate prefixes. Note that any route with a zero next-hop (0.0.0.0 for IPv4 or :: for IPv6) will get a label per-prefix since the router cannot reliably determine the next-hop. This example is a little artificial in this way, but it still demonstrates the feature.

```
R7#show bgp vpnv6 unicast vrf TOP nexthops
# Paths  Nexthop Address
Route Distinguisher: 214:7 (default for vrf TOP)
  20     ::FFFF:214.0.0.8
  7      FD00:10:7:10::10 (FE80::10) (TOP)
```

Nothing is networking is free, and these optimizations come with several limitations. Carrier supporting Carrier (CSC) is not a valid design when using these label aggregation features. Likewise, BGP PIC and iBGP multipath are not advertised to work either. The per-CE feature has even more limitations: routes can only be imported from BGP and cannot be eBGP multi-hop. To demonstrate some of these restrictions, we will try to enable VRF-aware LDP on the VRF TOP interface to support CSC. We can also try to the IPv4 labeled-unicast inside BGP, but we get the same message.

```
R7(config)#int gig2.570
R7(config-subif)#mpls ip
% Cannot configure CSC for vrf TOP, please remove the per-VRF label mode
configuration before configuring CSC
```

```

R7(config)#router bgp 214
R7(config-router)#address-family ipv4 vrf TOP
R7(config-router-af)#neighbor 10.7.10.10 send-label
% Cannot configure CSC for vrf TOP, please remove the per-VRF label mode
configuration before configuring CSC

```

We can configure three bogus static routes on CSR7 within the VRF. Two of them use CSR10's public address of FD00:10:7:10::10 and one of them uses FE80::10. Since the BGP next-hops are recursive using the LL address, the static route pointing to FE80::10 is allowed to share a label with the BGP prefixes from CSR10. This is confusing since the BGP label list for VPNv6 clearly shows the pre-recursive next-hop of the global address, but label 7020 is really associated with FE80::10 per the LFIB. The other two static routes use a new label bound to FD00:10:7:10::10 per the LFIB.

```

! CSR7
ipv6 route vrf TOP 2BAD::88:10:10/128 GigabitEthernet2.570 FD00:10:7:10::10

* 2BAD::88:10:100/128 via FD00:10:7:10::10, GigabitEthernet2.570, distance 1
* 2BAD::88:100:100/128 via FE80::10, GigabitEthernet2.570, distance 1

```

```

R7#show mpls forwarding-table labels 7013
Local      Outgoing  Prefix          Bytes Label  Outgoing  Next Hop

```

Label	Label	or Tunnel Id	Switched	interface	
7013	No Label	nh-id(4)	0	Gi2.570	FD00:10:7:10::10

R7#show mpls forwarding-table labels 7020

Local	Outgoing	Prefix	Bytes	Label	Outgoing	Next Hop
Label	Label	or Tunnel Id	Switched		interface	
7020	No Label	nh-id(3)	0		Gi2.570	FE80::10

Because prefixes are aggregated by labels, per-prefix counters no longer function. Since the per-VRF and per-next-hop methods both collapse LFIB entries into single (or few) entries, only aggregate counters are collected. The LFIB has no way to differentiate and makes no attempt. We know label 7005 represents all of VRF TOP for IPv4, so we can check counters for that only.

R1#ping 88.125.160.65 source 82.125.161.129 repeat 10000

R7#show mpls forwarding-table labels 7005

Local	Outgoing	Prefix	Bytes	Label	Outgoing	Next Hop
Label	Label	or Tunnel Id	Switched		interface	
7005	Pop Label	IPv4 VRF[V]	244614			aggregate/TOP

Likewise for the per-next-hop behavior configured for VPNv6, we can only account for packets on a per-next-hop basis.

R1#ping 2BAD:88:125:160:300::1 source 2BAD:82:125:160:400::1 repeat 1000

R7#show mpls forwarding-table interface gig2.570

Local	Outgoing	Prefix	Bytes	Label	Outgoing	Next Hop
Label	Label	or Tunnel Id	Switched		interface	
7013	No Label	nh-id(4)	0		Gi2.570	FD00:10:7:10::10
7020	No Label	nh-id(3)	254998		Gi2.570	FE80::10

We can still send traffic for the bogus routes and temporarily create a new loopback on CSR10 to respond. The counters for the second next-hop will increment because technically the LFIB still received an MPLS packet and performed a pop operation.

R1#ping 2BAD::88:10:100 source 2BAD:82:125:160:400::1 repeat 100

R7#show mpls forwarding-table interface gig2.570

Local	Outgoing	Prefix	Bytes	Label	Outgoing	Next Hop
Label	Label	or Tunnel Id	Switched		interface	
7013	No Label	nh-id(4)	11800		Gi2.570	FD00:10:7:10::10
7020	No Label	nh-id(3)	299484		Gi2.570	FE80::10

There is one final option which takes the per-VRF method and enhances it. Aggregates created on the PE, along with any connected routes, will all share a single label. This allows the SP to leak specific routes that may need their own labels for multipath, add-path, per-prefix counters, or any other feature not

supported with per-VRF or per-CE labels. The aggregate/connected routes behave like per-VRF label aggregates. On CSR7, we configured these label mode options on a per-VRF, per-AFI basis. On CSR8, we will summarily configure the per-VRF connected/aggregate feature for all VRFs and all AFIs for variety. We will also configure some IPv4 and IPv6 aggregates within the VRFs. Last, we redistribute the connected PE-CE transit link so that we have a combination of many “interesting” routes.

```
! CSR8
mpls label mode all-vrfs protocol all-afs vrf-conn-aggr

router bgp 214
 address-family ipv4 vrf BOTTOM
   redistribute connected
   aggregate-address 82.125.160.64 255.255.255.192
   aggregate-address 82.125.160.0 255.255.255.192

 address-family ipv6 vrf BOTTOM
   redistribute connected
   aggregate-address 2BAD:82:125:160:200::/71
   aggregate-address 2BAD:82:125:160::/71
```

We can see that VPNv4 has allocated label 8025 as an aggregate label for the connected transit link and aggregate addresses. Because the aggregates did not suppress longer-matches, the component routes are present as well, and with per-prefix labels.

```
R8#show bgp vpnv4 unicast vrf BOTTOM labels
  Network           Next Hop           In label/Out label
Route Distinguisher: 214:8 (BOTTOM)
 10.1.8.0/24         0.0.0.0             IPv4 VRF Aggr:8025/nolabel (BOTTOM)
 82.125.160.0/28     10.1.8.1            8005/nolabel
 82.125.160.0/26     0.0.0.0             IPv4 VRF Aggr:8025/aggregate (BOTTOM)
 82.125.160.16/28    10.1.8.1            8006/nolabel
 82.125.160.32/28    10.1.8.1            8007/nolabel
 82.125.160.48/28    10.1.8.1            8008/nolabel
 82.125.160.64/27    10.1.8.1            8009/nolabel
 82.125.160.64/26    0.0.0.0             IPv4 VRF Aggr:8025/aggregate (BOTTOM)
```

The LFIB for this label entry is identical to that seen for the per-VRF mode. This design isn’t very effective since all of the longer-matches are unsuppressed, but realistically many would be suppressed, making use of the aggregated labels to reduce LIB size.

```
R8#show mpls forwarding-table labels 8025 detail
Local      Outgoing  Prefix          Bytes Label  Outgoing  Next Hop

Label      Label      or Tunnel Id    Switched     interface
8019       Pop Label  IPv6 VRF[V]     0            aggregate/BOTTOM
          MAC/Encaps=0/0, MRU=0, Label Stack{}
          VPN route: BOTTOM
          No output feature configured
```

We can confirm the configuration and label value by checking the VRF details. Just like the per-VRF label mode, the per-VRF connected/aggregate option uses a single, predetermined label, so the VRF stores it.

```
R8#show vrf detail BOTTOM | include ^Address|label_alloc
Address family ipv4 unicast (Table ID = 0x2):
  VRF label allocation mode: vrf-conn-aggr (Label 8025)
Address family ipv6 unicast (Table ID = 0x1E000001):
  VRF label allocation mode: vrf-conn-aggr (Label 8019)
Address family ipv4 multicast not active
```

The feature is very similar on XR and is examined briefly. The configuration happens under BGP, which is a more appropriate place for it. On XRv1, we will enable the per-VRF mode for EIGRP IPv4 AFI and per-CE mode for the EIGRP IPv6 AFI. The topology is imperfect for validating these, but we can show that they are working.

```
! XRv1
router bgp 214
  vrf EIGRP
```

```

address-family ipv4 unicast
  label mode per-vrf
address-family ipv6 unicast
  label mode per-ce

```

After issuing these commands, we can verify it by checking the BGP label table. The label “type” shows whether we are using per-VRF, per-CE, or per-prefix. The default for IPv4/v6 and VPNV4/v6 AFI is per-prefix. Interestingly, we see per-VRF labels allocated for OSPF, EIGRP, and RIP, when we only configured it for EIGRP. We also see per-prefix labels for RD 214:101 and 214:106 (OSPF and RIP), but not RD 214:102 (EIGRP). The IOS XR documentation states *“Even if label mode is in use, per-vrf label is allocated for connected, aggregate, and local prefixes.”* This helps explain why we see aggregated, per-VRF labels in the BGP label table for VRFs we haven’t configured at all. In the case of OSPF, EIGRP, and RIP, they all included connected routes when redistributing into BGP, and so those routes were assigned the VRF aggregate label.

```

RP/0/0/CPU0:XRv1#show bgp label table

```

Label	Type	VRF/RD	Context

91023	IPv6 VRF Prefix	214:101	fd00:192:5:101::/64
91032	IPv6 VRF Prefix	214:101	::192:101:5:5/128
91033	IPv6 VRF Prefix	214:101	fd00:192:12:101::/64
91040	IPv6 Nexthop	EIGRP	1

For example, XRv1 has allocated label 91008 for EIGRP IPv6 prefixes that meet the condition outlined above, while using label 91040 for labels learned from each CE. The connected route uses the per-VRF label (green) while the EIGRP-learned routes from XRv3 (specifically FE80::13 as a next-hop) use the per-next-hop label (yellow). It is interesting to note that XR per-CE label allocation works with non-BGP protocols for PE-CE as we demonstrate below.

```

RP/0/0/CPU0:XRv1#show bgp vrf EIGRP ipv6 unicast labels | begin Network

```

Network	Next Hop	Rcvd Label	Local Label

```

Route Distinguisher: 214:102 (default for vrf EIGRP)

                        214.0.0.12      92008      nolabel

```

For EIGRP IPv4, we don't see any per-prefix or next-hop labels, implying that all EIGRP IPv4 prefixes share the per-VRF label. This is the expected behavior based on our configuration.

```

RP/0/0/CPU0:XRv1#show bgp vrf EIGRP labels | begin Network
  Network      Next Hop      Rcvd Label      Local Label
Route Distinguisher: 214:102 (default for vrf EIGRP)

```

In the case of OSPF, where we didn't change the label mode at all, we can see individual, per-prefix labels for all truly OSPF-learned routes. Routes locally originated into BGP, such as the connected PE-CE link to XRv3 or the sham-link endpoint, use the per VRF label 91007 identified in the label table viewed earlier. This is efficient because the VPN FIB needs to be consulted anyway, so allocating 1 label for N connected/aggregate routes conserves label resources.

```

RP/0/0/CPU0:XRv1#show bgp vrf OSPF labels | begin Network
  Network      Next Hop      Rcvd Label      Local Label

```

```

```

We can drill into the details of a single label as well. Using 91040, since it is the most interesting, we can see the table details displayed in verbose fashion, as well as the label's age. The label context contains a reference ID to the actual next-hop. We can check the nexthop-set with BGP to see what "1" means, and as expected, it references FE80::13.

```

RP/0/0/CPU0:XRv1#show bgp label 91040
BGP Label Entry: 91040
  Last Updated : MON 03 21:09:07.386 (00:33:19 ago)
  Label Type   : IPv6 Nexthop
  VRF/RD       : EIGRP
  Label Context: 1
  Refcount     : 2

```

```

RP/0/0/CPU0:XRv1#show bgp vrf EIGRP ipv6 unicast nexthop-set
  Resilient per-CE nexthop set, ID 1
  Number of nexthops 1, Label 91040, Flags 0x1
  Nexthops:
  fe80::13

```

Looking at a per-prefix label, we see similar information, with the addition of the prefix to which the label is bound. XE did not appear to support these kind of label-specific show commands.

```

RP/0/0/CPU0:XRv1#show bgp label 91020
BGP Label Entry: 91020
  Last Updated : MON 01 23:04:58.145 (1d22h ago)
  Label Type   : IPv4 VRF Prefix
  VRF/RD       : 214:104
  Label Context: 192.5.104.0/24
  Refcount     : 1

```

We can view the label allocations in summary form as well. Because XR supports so many label varieties, we can perform a quick check to see the quantity of each label allocated. As an example, one per-CE IPv6 label was allocated, which is used by the EIGRP IPv6 VPN. There are zero for IPv4 because we did not enable that anywhere.

```
RP/0/0/CPU0:XRv1#show bgp label summary
```

Label Alloc Type	Labels
GBL IPv4 Prefix	0
VRF IPv4 Prefix	0
VPN IPv4 Prefix	0
CE IPv4 Nexthop	0
VRF IPv4 Table	3
GBL IPv6 Prefix	0
VRF IPv6 Prefix	0
VPN IPv6 Prefix	0
CE IPv6 Nexthop	1
VRF IPv6 Table	2
ASBR Nexthop	0
TOTAL	6

Checking the data plane, we can see these labels programmed into the LFIB. Because the label refers to a remote VPN prefix, referencing the label by itself did not work, but using a label range did. We also look at a per-VRF label, which is identified as such in the LFIB, whereby the per-nexthop label has “No ID” that makes it unique. The aggregate label LFIB entry essentially directs the router to perform a VPN FIB lookup.

```
RP/0/0/CPU0:XRv1#show mpls forwarding labels 91039 91040
```

Local Label	Outgoing Label	Prefix or ID	Outgoing Interface	Next Hop	Bytes Switched
91040	Unlabelled	No ID	Gi0/0/0/0.102	fe80::13	0
	Aggregate	No ID	EIGRP		0

```
RP/0/0/CPU0:XRv1#show mpls forwarding labels 91007
```

Local Label	Outgoing Label	Prefix or ID	Outgoing Interface	Next Hop	Bytes Switched
91007	Aggregate	OSPF: Per-VRF Aggr[V]	OSPF	\	12488

On XRv2, we will perform a more complex example using RPL. XRv2 learns 4 total routes via BGP between IPv4 and IPv6 from CSR5. Currently, each one has a different, per-prefix label. Only examining IPv4, we want to use a per-VRF label for all non-host routes.

```
RP/0/0/CPU0:XRv2#show bgp label table | include 214:104
92013   IPv4 VRF Prefix  214:104          192.12.104.0/24
92014   IPv4 VRF Prefix  214:104          192.104.5.5/32
92015   IPv6 VRF Prefix  214:104          ::192:104:5:5/128
92016   IPv6 VRF Prefix  214:104          fd00:192:12:104::/64
```

Ideally, we should see 192.12.104.0/24 to the per-VRF value, while CSR5's loopback still has a per-prefix label. This might be useful to have different LFIB counters or for performance reasons, since per-VRF label requires a FIB (not LFIB) lookup after the bottom label is removed.

```
! XRv2
prefix-set PS_HOST_ROUTES
  0.0.0.0/0 ge 32
end-set

route-policy RPL_PER_PREFIX_IF_MATCH($PS)
  if destination in $PS then
    set label-mode per-prefix
  else
    set label-mode per-vrf
  endif
end-policy

router bgp 214
  vrf BGP
  address-family ipv4 unicast
  label mode route-policy RPL_PER_PREFIX_IF_MATCH(PS_HOST_ROUTES)
```

Looking at the label table again, we only see 3 routes with per-prefix labels within RD 214:104. The one IPv4 route remaining is CSR5's loopback, which is a host route, and should have a per-prefix label.

```
RP/0/0/CPU0:XRv2#show bgp label table | include 214:104
92014   IPv4 VRF Prefix  214:104          192.104.5.5/32
92015   IPv6 VRF Prefix  214:104          ::192:104:5:5/128
92016   IPv6 VRF Prefix  214:104          fd00:192:12:104::/64
```

We have a new entry in the table for the IPv4 VRF table for the BGP VRF. The label allocated was 92029, and the details indicate it is only a few minutes old. BGP also indicates that the PE-CE link to CSR5 and the backdoor link between CSR5 and XRv3 are both using this label.

```
RP/0/0/CPU0:XRv2#show bgp label table | include BGP
92029   IPv4 VRF Table      BGP      -
```

```
RP/0/0/CPU0:XRv2#show bgp label 92029
BGP Label Entry: 92029
  Last Updated : MON 03 22:03:21.159 (00:02:50 ago)
  Label Type   : IPv4 VRF Table
  VRF/RD       : BGP
  Refcount     : 2
```

```
RP/0/0/CPU0:XRv2#show bgp vrf BGP labels | include 92029
*> 192.5.104.0/24      192.12.104.5      nolabel      92029
*> 192.12.104.0/24     192.12.104.5      nolabel      92029
```

If we create a dummy prefix on CSR5 with a mask of /31, this route is also included in the per-VRF label. We can see the prefix bound to label 92029 on XRv2 as we expect.

```
! CSR5
interface Loopback104
 ip address 192.104.55.55 255.255.255.254 secondary
```

```
RP/0/0/CPU0:XRv2#show bgp vrf BGP labels | include 92029
*> 192.5.104.0/24      192.12.104.5      nolabel      92029
*> 192.12.104.0/24     192.12.104.5      nolabel      92029
*> 192.104.55.54/31    192.12.104.5      nolabel      92029
```

38.3 VRF selection for traffic leaking

Although route-leaking is a little more straightforward (discussed later), we can also forcibly move traffic between VRFs, VRF to global, and global to VRF using other techniques. IOS and IOS-XE platforms support three: VRF selection, VRF autoclassify, and VRF receive with PBR. All three are discussed, but only the last one works on the CSR1000v.

VRF selection does not appear to be supported on the CSR1000v as it is somewhat hardware specific. There isn't anything more to say about this since the command doesn't work. Normally, any traffic coming from the specified source would have its destination IP address looked up in the specified VRF, much like the PBR approach we will evaluate later.

```
R2(config)#vrf selection source 10.2.9.0 255.255.255.0 vrf VIA_XRV4
% VRF Select: failed to add config
```

VRF autoclassify should work, but the system tries to add dynamic route-maps with spaces in the name. I was not able to find a debug command that actually shows the route-map name, but I can see the system try to make them. This feature does not work as a result of the route-maps not being properly created. With the exception of the command that doesn't work, the configuration below is valid.

```
! CSR2
interface GigabitEthernet2.529
 description VRF SELECT USING SECONDARIES
```

```
encapsulation dot1Q 3529
ip address 10.2.9.2 255.255.255.0 secondary vrf VIA_XRV4
ip address 10.9.2.2 255.255.255.0 secondary vrf VIA_CSR6
ip address 2.2.2.2 255.255.255.0
```

```
R2(config-subif)#ip vrf autoclassify source
```

```
% Spaces not Allowed in route-map names
```

```
% Spaces not Allowed in route-map names
```

```
R2#debug route-map api
```

```
RMAP: App:IPVRF; Call to:rmap_api_reg_app() -- 3
```

```
RMAP: App:IPVRF; Call to: rmap_api_create() -- 3
```

```
RMAP: App:IPVRF; Call to: rmap_api_create() -- 3
```

Ultimately, no route-maps are made, IP VRF auto-classify is not listed as an input feature on that interface, and PBR is not active. The feature may not be fully supported on this IOS-XE version; always check the official Cisco release notes for your current version.

```
R2#show route-map dynamic
```

```
Current active dynamic routemaps = 0
```

```
R2#show ip interface gig2.529 | include Input_feat
```

```
Input features: MCI Check
```

```
R6#show ip policy
```

```
Interface      Route map
```

```
[no output]
```

What does work is the “receive VRF” selection using manual PBR. Before beginning, note that you must enable PBR on the interface or configure VRF Select before configuring the VRF receive feature. Since VRF Select is not supported, we will create a PBR policy.

```
R2(config-subif)#ip vrf receive VIA_XRV4
```

```
% Need to enable Policy Based Routing or VRF Select on the interface first
```

Specifically, we want to take traffic from 10.2.9.0/24 and use VRF VIA_XRV4 for the route lookup. We want to do the same for 10.9.2.0/24 but use VRF VIA_CSR6 for the route lookup. We can be even more specific; rather than simply select a VRF for a normal routing lookup, we can cross VRFs while also specifying a next-hop. To demonstrate this, the first case uses the ordinary VRF lookup; packets arriving with source 10.2.9.0/24 will be routed normally, but the destination address will be looked up in VIA_XRV4. For sources 10.9.2.0/24, the regular routing process is overridden and the next-hop is set to CSR6, but is also allowed to cross VRFs. The effect is the same, since we can take traffic from the global table (the interface is not in a VRF) and leak it into other tables.

```
! CSR2
```

```

ip access-list standard ACL_VIA_CSR6
  permit 10.9.2.0 0.0.0.255
ip access-list standard ACL_VIA_XRV4
  permit 10.2.9.0 0.0.0.255

route-map RM_VRF_SELECTION permit 10
  match ip address ACL_VIA_XRV4
  set vrf VIA_XRV4
route-map RM_VRF_SELECTION permit 20
  match ip address ACL_VIA_CSR6
  set ip vrf VIA_CSR6 next-hop 10.2.6.6

interface GigabitEthernet2.529
  encapsulation dot1Q 3529
  ip vrf receive VIA_XRV4
  ip vrf receive VIA_CSR6
  ip address 2.2.2.2 255.255.255.0
  ip policy route-map RM_VRF_SELECTION

```

The problem with this approach is that it doesn't consider the return traffic. Even if XRv4 and CSR6 had return routes for 10.2.9.0/24 and 10.9.2.0/24 respectively, CSR2 will receive them on VRF enabled interfaces, perform a route lookup on the destination, and drop the traffic. We can override this with PBR in the return path to leak traffic from a VRF to the global table. Using similar techniques, we use an extended ACL to match destinations (for the return traffic). For CSR6, we will instruct the policy to perform a normal route lookup in the global table, which means CSR2 will need a route to 10.9.2.0/24 via 2.2.2.9. For XRv4, we will use PBR to avoid that by statically defining the next-hop in the PBR policy to 2.2.2.9. We also specify the keyword "global" so that the lookup on that hard-coded next-hop happens outside of the incoming link VRF, which was VIA_XRV4. We don't need to specify any "receive" VRFs on those interfaces since the traffic isn't being considered for migration into another VRF, but just the global table.

```

! CSR2
ip access-list extended ACL_RETURN_CSR6
  permit ip any 10.9.2.0 0.0.0.255
ip access-list extended ACL_RETURN_XRV4
  permit ip any 10.2.9.0 0.0.0.255

route-map RM_FROM_XRV4 permit 10
  match ip address ACL_RETURN_XRV4
  set ip global next-hop 2.2.2.9
route-map RM_FROM_CSR6 permit 10
  match ip address ACL_RETURN_CSR6
  set global

ip route 10.9.2.0 255.255.255.0 GigabitEthernet2.529 2.2.2.9

interface GigabitEthernet2.526

```

```

vrf forwarding VIA_CSR6
ip policy route-map RM_FROM_CSR6

interface GigabitEthernet2.524
vrf forwarding VIA_XRV4
ip policy route-map RM_FROM_XRV4

```

This is certainly a lot of manual labor. Fortunately, the “set global” and “set vrf” commands are highly scalable since we can just select tables for lookups without statically defining next-hops. However, this technique assumes that the VRF table has a route that can forward the leaked packets. Any combination of static and dynamic routing can be used to achieve this. Before testing, I will clear all counters on the PBR route-maps and enabling PBR debugs.

```

R2#clear route-map counters RM_FROM_XRV4
R2#clear route-map counters RM_FROM_CSR6
R2#clear route-map counters RM_VRF_SELECTION

R2#debug ip policy
Policy routing debugging is on

```

A quick verification shows that PBR is properly applied on the correct interfaces. We also configure some basic secondary addresses (loopbacks would work also) along with a static default route. This is only needed so CSR9 can encapsulate the IP packets to CSR2’s MAC address, allowing PBR to take over once the layer 2 encapsulation is removed. These are effectively our test source addresses.

```

R2#show ip policy
Interface      Route map
Gi2.524        RM_FROM_XRV4
Gi2.526        RM_FROM_CSR6
Gi2.529        RM_VRF_SELECTION

! CSR9
interface GigabitEthernet2.529
encapsulation dot1Q 3529
ip address 10.9.2.9 255.255.255.0 secondary
ip address 10.2.9.9 255.255.255.0 secondary
ip address 2.2.2.9 255.255.255.0

ip route 0.0.0.0 0.0.0.0 GigabitEthernet2.529 2.2.2.2

```

Unfortunately, the CSR1000v (CSR2) is not revealing any PBR debugs at all when we send some test traffic from CSR9 to CSR6. We source the traffic from one of CSR9’s secondary addresses that is mapped to the VIA_CSR6 VPN. We can check the route-map counters for additional confirmation. Notice that no traffic was matched for the first SELECTION match clause, which was for VIA_XRV4. Likewise, no traffic has entered from XRV4 yet. The successful ping and route-map counters are indicative of a successful configuration.

```
R9#ping 10.2.6.6 source 10.9.2.9
Type escape sequence to abort.
Sending 5, 100-byte ICMP Echos to 10.2.6.6, timeout is 2 seconds:
Packet sent with a source address of 10.9.2.9
!!!!
Success rate is 100 percent (5/5), round-trip min/avg/max = 4/6/10 ms
```

```
R2#show route-map | include ^route-map|Policy
route-map RM_VRF_SELECTION, permit, sequence 10
  Policy routing matches: 0 packets, 0 bytes
route-map RM_VRF_SELECTION, permit, sequence 20
  Policy routing matches: 5 packets, 590 bytes
route-map RM_FROM_XRV4, permit, sequence 10
  Policy routing matches: 0 packets, 0 bytes
route-map RM_FROM_CSR6, permit, sequence 10
  Policy routing matches: 5 packets, 590 bytes
```

We retest from CSR9, this time sending traffic to XRV4. We will send more packets so the counters look different. Also note that there is nothing stopping us from using more advanced PBR matching, like TCP/UDP ports, DSCP, etc. Unlike auto-classify or VRF select, we gain more flexibility from this approach despite the poorly scaling configurations.

```
R9#ping 10.2.14.14 source 10.2.9.9 repeat 10
Type escape sequence to abort.
Sending 10, 100-byte ICMP Echos to 10.2.14.14, timeout is 2 seconds:
Packet sent with a source address of 10.2.9.9
!!!!!!!!!!!!
Success rate is 100 percent (10/10), round-trip min/avg/max = 2/12/19 ms
```

```
R2#show route-map | include ^route-map|Policy
route-map RM_VRF_SELECTION, permit, sequence 10
  Policy routing matches: 10 packets, 1180 bytes
route-map RM_VRF_SELECTION, permit, sequence 20
  Policy routing matches: 5 packets, 590 bytes
route-map RM_FROM_XRV4, permit, sequence 10
  Policy routing matches: 10 packets, 1180 bytes
route-map RM_FROM_CSR6, permit, sequence 10
  Policy routing matches: 5 packets, 590 bytes
```

38.4 VRF route leaking

Both XE and XR can leak routes between VRFs as well. BGP is typically required for this. On CSR6 and XRV4, we will leak routes from the global table to and from the different customer VRFs. Since we have been using CSR6 and XRV4 for CE routers, they have many VRFs with many diverse routes. Their links to CSR2 are in the global table and are currently used for the VRF traffic leaking with PBR. Both CSR6 and XRV4 have a static route (configured earlier) to 10.0.0.0/8 via CSR2 in their global tables. This is entirely disconnected from the MPLS L3VPN tests conducted earlier. There are two important side notes with

route leaking. First, the VRF must have an RD. If it doesn't the parser gives you an error message. This is because the routes are treated like VPN routes and need to be stored separately in the BGP table.

```
R6(config-vrf-af)#export ipv4 unicast 10 map RM_VRF_TO_GLOBAL
%vrf ISIS does not have "rd" configured, please configure "rd" before
configuring export route-map
```

Second, these commands only have visibility to routes in the BGP RIB. If the route isn't in global BGP, it cannot be imported to a VRF. If the route isn't in VPN BGP, it cannot be exported to the global table. For this reason, we will work with the pre-existing BGP VRF since it already has BGP-learned routes, which implies it has an RD configured. When configuring this feature, we can configure an upper-bound on the number of prefixes imported. Since we are moving routes between tables, they are being copied, so the boundary condition is a safety check. First, we will leak all VPNv4 BGP host routes within the BGP VPN into the global table. The usage of RT's is kind of odd since it makes no sense, but is actually required for the feature to work. If you forget the RTs, iBGP routes appear to work, but locally-originated and eBGP learned routes do not. Overall, the behavior is simply inconsistent if you forget the add RTs.

```
! CSR6
ip prefix-list PL_HOST_ROUTES seq 5 permit 0.0.0.0/0 ge 32

route-map RM_VRF_TO_GLOBAL permit 10
 match ip address prefix-list PL_HOST_ROUTES

vrf definition BGP
 rd 214:104
 address-family ipv4
   export ipv4 unicast 10 map RM_VRF_TO_GLOBAL
   route-target export 1:1
   route-target import 1:1
```

After applying this configuration, we see several host-routes in the BGP global table, as well as the routing table, since these are the best available routes. The routing table annotates that the next-hops are in VRF BGP, not the global table. Notice that all BGP paths are exported, not just the best paths. Since CSR6's local loopback prefix is directly connected, there is no next-hop, but the packet is delivered locally to the router.

```
R6#show bgp ipv4 unicast | begin Network
```

	Network	Next Hop	Metric	LocPrf	Weight	Path
* i	192.104.5.5/32	192.6.104.14		100	0	214 104 ?
*>		192.4.104.4			0	214 214 ?
*>	192.104.6.6/32	0.0.0.0	0		32768	?
* i	192.104.13.13/32	192.6.104.14		100	0	214 104 ?
*>		192.4.104.4			0	214 214 ?
*>i	192.104.14.14/32	192.6.104.14	0	100	0	?

```

R6#show ip route bgp | begin Gate
Gateway of last resort is not set
    192.104.5.0/32 is subnetted, 1 subnets
B       192.104.5.5 [20/0] via 192.4.104.4 (BGP), 00:01:56
    192.104.6.0/32 is subnetted, 1 subnets
B       192.104.6.6 is directly connected, 00:01:30, Loopback104
    192.104.13.0/32 is subnetted, 1 subnets
B       192.104.13.13 [20/0] via 192.4.104.4 (BGP), 00:01:56
    192.104.14.0/32 is subnetted, 1 subnets
B       192.104.14.14 [200/0] via 192.6.104.14 (BGP), 00:01:35

```

The details of the BGP route in the global table indicate that it was imported from VRF BGP, which includes the entire VPNv4 prefix, with the RD and VRF identified. All attributes of the route, to include communities, are carried over. Communities like SoO and RT are not terribly useful in global BGP.

```

R6#show bgp ipv4 unicast 192.104.5.5/32
BGP routing table entry for 192.104.5.5/32, version 3
Paths: (2 available, best #2, table default)
  Not advertised to any peer
  Refresh Epoch 1
  214 104, imported path from 214:104:192.104.5.5/32 (BGP)
    192.6.104.14 from 192.6.104.14 (14.14.14.14)
      Origin incomplete, localpref 100, valid, internal
      Extended Community: SoO:214:4 RT:1:1
      rx pathid: 0, tx pathid: 0
  Refresh Epoch 1
  214 214, imported path from 214:104:192.104.5.5/32 (BGP)
    192.4.104.4 from 192.4.104.4 (214.0.0.4)
      Origin incomplete, localpref 100, valid, external, best
      Extended Community: RT:1:1
      rx pathid: 0, tx pathid: 0x0

```

We can also move routes in the opposite direction, taking them from the global table into the VRF table. We will use a match-all route-map and not set a prefix limit. This is the most dangerous approach but is shown here for variety; it effectively permits all VPNv4 routes to be leaked to the global table. We must advertise the static 10.0.0.0/8 route into BGP and do so with a simple network statement. There is no need to specify RTs when importing to VRF from global.

```

! CSR6
route-map RM_MATCH_ALL permit 10

router bgp 104
  address-family ipv4
    network 10.0.0.0

vrf definition BGP
  address-family ipv4

```

```
import ipv4 unicast map RM_MATCH_ALL
```

First, we verify that advertising 10.0.0.0/8 into the global table was successful. The route is marked as “af-import” to signify that a VRF is importing this route. Then, we check the VRF BGP table for the route and find it. Since the route was already imported to VRF BGP, it cannot be imported again, explaining the “no-import” flag. It is interesting to note that the VRF treats this route as external despite having an AS path length of 0. I assume this is done so that the route can be advertised to iBGP peers.

```
R6#show bgp ipv4 unicast 10.0.0.0
BGP routing table entry for 10.0.0.0/8, version 5
Paths: (1 available, best #1, table default)
  Not advertised to any peer
  Refresh Epoch 1
  Local
    10.2.6.2 from 0.0.0.0 (6.6.6.6)
      Origin IGP, metric 0, localpref 100, weight 32768, valid, sourced,
local, af-export(1), best
      rx pathid: 0, tx pathid: 0x0

R6#show bgp vpnv4 unicast vrf BGP 10.0.0.0
BGP routing table entry for 214:104:10.0.0.0/8, version 18
Paths: (1 available, best #1, table BGP)
  Advertised to update-groups:
    3          4
  Refresh Epoch 1
  Local, imported path from 10.0.0.0/8 (global)
    10.2.6.2 (via default) from 0.0.0.0 (6.6.6.6)
      Origin IGP, metric 0, localpref 100, weight 32768, valid, external, no-
import, no-import, best
      rx pathid: 0, tx pathid: 0x0
```

We can check the summary information of these import/export policies within the VRF BGP table. It shows the route-map name, AFI, and prefix counts. The default limit is 1000. Notice that the 4 prefixes (loopbacks) exported from VRF BGP to global only count as 4 and not 6; we learned 6 unique paths but this is a per-prefix counter, which does not account for alternate paths.

```
R6#show bgp vpnv4 unicast vrf BGP | include t_Map
Import Map: RM_MATCH_ALL, Address-Family: IPv4 Unicast, Pfx Count/Limit:
1/1000
Export Map: RM_VRF_TO_GLOBAL, Address-Family: IPv4 Unicast, Pfx Count/Limit:
4/10
```

At this point, we should have reachability from CSR9 to those leaked BGP loopbacks. We already verified that CSR6’s global table had the remote loopbacks, but we also have to verify that the VRF table has the 10.0.0.0/8 summary. The next-hop is in the global (or “default”) table which allows CSR6 to move packets across tables.

```
R6#show ip route vrf BGP 10.0.0.0
```

Routing Table: BGP

```

```

```
rx pathid: 0, tx pathid: 0x0
```

We can test connectivity from CSR6 to CSR5, being sure to specify a valid source address on CSR6. The route lookup occurs in the global table, and CEF doesn't make any special note about the next-hop of CSR4 (Although we know 192.4.104.4 is within VRF BGP, not the global table).

```
R6#ping 192.104.5.5 source 10.2.6.6
```

```
Type escape sequence to abort.
```

```
Sending 5, 100-byte ICMP Echos to 192.104.5.5, timeout is 2 seconds:
```

```
Packet sent with a source address of 10.2.6.6
```

```
!!!!
```

```

```

```
recursive via 192.4.104.4
```

```
attached to GigabitEthernet2.104
```

When we test connectivity to XRv4's loopback, the ping fails. This is because the 10.0.0.0/8 route was imported as an eBGP route, which means it can be advertised to iBGP peers. The next-hop is unchanged by default. Normally, this would just mean that XRv4 would select the path via CSR3 instead. The key phrase below is "import dampened" which means there is some kind of routing problem with this BGP

prefix. We expected 10.2.6.2 to be inaccessible, as explained earlier, but this new “dampened” word is different.

```
RP/0/0/CPU0:XRv4#show bgp vpv4 unicast vrf BGP 10.0.0.0/8 | begin Paths
Paths: (2 available, best #1)
  Not advertised to any peer
  Path #1: Received by speaker 0
  Not advertised to any peer
  214 104
    192.3.104.3 from 192.3.104.3 (214.0.0.3)
      Origin IGP, localpref 100, valid, external, best, group-best, import-
candidate, import dampened
      Received Path ID 0, Local Path ID 1, version 2786
  Path #2: Received by speaker 0
  Not advertised to any peer
  Local
    10.2.6.2 (inaccessible) from 192.6.104.6 (6.6.6.6)
      Origin IGP, metric 0, localpref 100, valid, internal, import dampened
      Received Path ID 0, Local Path ID 0, version 0
```

The issue is that the route to 10.2.6.2 is 10.0.0.0/8, which creates recursive routing logic error on XRv4. It generates occasional syslog messages to warn us about this. We would not have this issue if the next-hop was not covered by the aggregate in question.

```
! XRv4
ipv4_rib[1144]: %ROUTING-RIB-7-SERVER_ROUTING_DEPTH : Recursion loop looking
up prefix 10.2.6.2 in Vrf: "BGP" Tbl: "default" Safi: "Unicast" added by bgp
ipv4_rib[1144]: %ROUTING-RIB-5-TABLE_NH_DAMPED : Nexthops in Vrf: BGP Tbl:
default (0xe0000011) Safi: Unicast are getting damped
```

To fix it, we apply next-hop-self to CSR6’s neighbor configuration towards XRv4. XRv4 then learns this route via the backdoor, as expected, and reachability is achieved. Normally, we would never need next-hop-self in this situation, but since the route was viewed as eBGP, the next-hop was not changed when it was advertised to an iBGP neighbor.

```
! CSR4
router bgp 104
  address-family ipv4 vrf BGP
    neighbor 192.6.104.14 next-hop-self
```

```

Packet sent with a source address of 10.2.6.6
!!!!
Success rate is 100 percent (5/5), round-trip min/avg/max = 3/5/14 ms
```

Tying this in with the existing VRF traffic leaking, CSR9 now has reachability to all 4 of the VRF BGP loopbacks. The summary results are shown below; provided CSR2 can somehow get the traffic back and forth between CSR9 and CSR6 (which it can), there should be no problems. CSR6 will perform route lookups in the global FIB on traffic coming inbound from CSR2, but the next-hops will be inside the BGP VRF (either towards CSR4 or XRv4). Returning traffic will always go to 10.9.2.9, which is in the global table. Again, the FIB does not make any special annotation of the VRF since it just needs to switch packets between interfaces and add layer 2 encapsulation as needed.

```
R6#show ip cef vrf BGP 10.9.2.9 detail
10.0.0.0/8, epoch 0, flags [rib only nolabel, rib defined all labels]

```

```
R9#ping 192.104.14.14 source 10.9.2.9
[snip]
Success rate is 100 percent (5/5), round-trip min/avg/max = 3/6/15 ms
```

We will examine the same feature on XRv4 now. Fortunately, XR does not require the RT configuration to export routes from a VRF to a global table. Using the same logic as before (except with a parameterized RPL), we can match all host routes in the BGP VRF. We also need to specify a BGP RID since there are no available IPv4 unicast global loopbacks; without a RID, BGP cannot select a best-path as it cannot properly initialize. We also must initialize the global IPv4 unicast AFI on XRv4, which is

something we haven't done yet. The "else drop" stanza is technically unnecessary since the RPL will drop all routes not explicitly passed, but I add it for completeness.

```
! XRv4
vrf BGP
  address-family ipv4 unicast
    export to default-vrf route-policy RPL_LEAK(PS_VRF_TO_GLOBAL)

prefix-set PS_VRF_TO_GLOBAL
  0.0.0.0/0 ge 32
end-set

route-policy RPL_LEAK($PS)
  if destination in $PS then
    pass
  else
    drop
  endif
end-policy

router bgp 104
  bgp router-id 14.14.14.14
  address-family ipv4 unicast
```

Looking at the BGP details, we can see the 4 loopbacks inside the global table now. The BGP details of a specific prefix don't specify in what VRF the next-hop lies, but it does list the source VRF, which implies the next-hop is accessible inside that VRF. The route is marked as "imported" much like a normal VPNv4 route would when using RTs. The IPv4 unicast RIB specifies that the next-hop is in VRF BGP, which is correct. The outputs in XR are similar to XE and nicely detail the route leaking operation.

```
RP/0/0/CPU0:XRv4#show bgp ipv4 unicast | begin Network
      Network      Next Hop      Metric LocPrf Weight Path
*> 192.104.5.5/32    192.3.104.3                      0 214 104 ?

Network	Neighbor	Route Distinguisher	Source VRF
*> 192.104.5.5/32	192.3.104.3	214:104	BGP
*> 192.104.13.13/32	192.3.104.3	214:104	BGP

Next, we will configure XRv4 to import its static route of 10.0.0.0/8 from the global table to the BGP VRF table. The configuration is very similar to XE; there are no RTs required. We will use redistribution to advertise the static route into BGP for variety.

```
! XRv4
vrf BGP
  address-family ipv4 unicast
    import from default-vrf route-policy RPL_LEAK(PS_GLOBAL_TO_VRF)

prefix-set PS_GLOBAL_TO_VRF
  10.0.0.0/8
end-set

router bgp 104
  address-family ipv4 unicast
    redistribute static
```

After configuring this, we can verify that the static route was properly redistributed into BGP IPv4 unicast. After that, it becomes candidate for import into VRF BGP. We verify that the export operation was successful, and also note that it is treated as an eBGP route. XR specifically marks this as an “extranet” route since it was imported from another routing table; specifically, it lists the source VRF as

“default”, which means global. XRv4 also learns the 10.0.0.0/8 prefix via CSR3 (PE) and CSR6 (backdoor), but they are not best paths due to the weight attribute.

```

```

The only significant result of using redistribution instead of the network statement is that CSR3 still prefers the iBGP route to 10.0.0.0/8 from CSR4 over the eBGP route from XRv4. This is because origin IGP is preferred over incomplete. This isn't a big deal, but is interesting to note as it changes the traffic pattern.

XR clearly annotates the next-hop VRF in the FIB. When performing a global lookup on XRv4 for CSR5's loopback, the VRF associated with the next-hop is displayed. This is probably just a cosmetic difference since XE also "knows" the VRF of the next-hop. The same is true for the VRF-aware FIB lookup towards 10.0.0.0/8, where the VRF containing the next-hop is "default".

```

```

Before testing connectivity from CSR9, we need to make one additional modification to the policies on CSR2. Currently, when packets arrive from CSR9 with a source inside 10.2.9.0/24, the router doesn't actually forwarding the traffic, but just sets a VRF for the route lookup. Sending traffic from CSR9's address in that range to any loopback will fail since the VIA_XRV4 table does not have a route for those prefixes.

```

R2#show route-map RM_VRF_SELECTION
route-map RM_VRF_SELECTION, permit, sequence 10
Match clauses:
ip address (access-lists): ACL_VIA_XRV4
Set clauses:

```

```

vrf VIA_XRV4
Policy routing matches: 98 packets, 11564 bytes
route-map RM_VRF_SELECTION, permit, sequence 20
Match clauses:
  ip address (access-lists): ACL_VIA_CSR6
Set clauses:
  ip vrf VIA_CSR6 next-hop 10.2.6.6
Policy routing matches: 99 packets, 11394 bytes

R2#show ip cef vrf VIA_XRV4 192.104.14.14
0.0.0.0/0
no route

```

To solve it, a VRF-aware static default route is added to CSR2. This means that after the policy-based lookup occurs, the VRF-aware FIB can forward traffic to XRv4. We could also run BGP or IGP with CSR2 to exchange routing information, but the static route is quick and easy.

```

! CSR2
ip route vrf VIA_XRV4 0.0.0.0 0.0.0.0 GigabitEthernet2.524 10.2.14.14

R2#show ip cef vrf VIA_XRV4 192.104.14.14
0.0.0.0/0
nexthop 10.2.14.14 GigabitEthernet2.524

```

CSR9 can now reach XRv14's loopback using 10.2.9.2 as a source, but no other loopbacks are reachable. This is due to the asymmetric routing that occurs. In this example, CSR9 cannot reach CSR6's loopback.

```

R9#ping 192.104.14.14 source 10.2.9.9
Type escape sequence to abort.
Sending 5, 100-byte ICMP Echos to 192.104.14.14, timeout is 2 seconds:
Packet sent with a source address of 10.2.9.9
!!!!
Success rate is 100 percent (5/5), round-trip min/avg/max = 2/5/19 ms

R9#ping 192.104.6.6 source 10.2.9.9
Type escape sequence to abort.
Sending 5, 100-byte ICMP Echos to 192.104.6.6, timeout is 2 seconds:
Packet sent with a source address of 10.2.9.9
.....
Success rate is 0 percent (0/5)

```

Considering that the traffic is probably reaching CSR6's loopback (the BGP routing is correct), the issue is with the return flow. We quickly verify that traffic reaching XRv4 for CSR6's loopback is routed to CSR6, as expected.

```

RP/0/0/CPU0:XRv4#show cef ipv4 192.104.6.6/32

```

```

192.104.6.6/32, version 26, internal 0x5000001 0x0 (ptr 0xa1416df4) [1], 0x0
(0x0), 0x0 (0x0)
local adjacency 192.6.104.6
Prefix Len 32, traffic index 0, precedence n/a, priority 4
via 192.6.104.6, 3 dependencies, recursive [flags 0x6000]
path-idx 0 NHID 0x0 [0xa1416b74 0x0]
next hop VRF - 'BGP', table - 0xe0000011
next hop 192.6.104.6 via 192.6.104.6/32

```

When CSR6 sends the reply packet back to 10.2.9.2, it follows its local static route towards CSR2.

```

R6#show ip cef vrf BGP 10.2.9.2
10.0.0.0/8
nexthop 10.2.6.2 GigabitEthernet2.526

```

The issue is that CSR2 does not have an inbound PBR policy to account for traffic to this destination. When the PBR lookup fails, CSR2 attempts to perform a normal VRF-aware FIB lookup, yet has no routing entry for it either.

```

R2#show route-map RM_FROM_CSR6
route-map RM_FROM_CSR6, permit, sequence 10
Match clauses:
ip address (access-lists): ACL_RETURN_CSR6
Set clauses:
global
Policy routing matches: 93 packets, 10842 bytes

```

```

R2#show access-list ACL_RETURN_CSR6
Extended IP access list ACL_RETURN_CSR6
10 permit ip any 10.9.2.0 0.0.0.255

```

```

R2#show ip cef vrf VIA_CSR6 10.2.9.2
0.0.0.0/0
no route

```

We can fix this problem by adding another entry to the ACL to account for 10.2.9.0/24 sources, which essentially permits asymmetric routing to work. More interestingly, we can add a static VRF-aware route with a global next-hop for this destination. When the PBR fails to match the incoming traffic to perform a lookup in the global VRF, CSR2 performs a lookup in the VRF VIA_CSR6 routing table. The static route is used, which essentially directs traffic for this destination towards CSR9's address in the global table.

```

! CSR2
ip route vrf VIA_CSR6 10.2.9.0 255.255.255.0 GigabitEthernet2.529 2.2.2.9
global

```

```

R2#show ip cef vrf VIA_CSR6 10.2.9.2
10.2.9.0/24

```

nexthop 2.2.2.9 GigabitEthernet2.529

If the asymmetry was happening in the other direction, we will have the same problem on CSR2's interface to XRv4. We can test this by sending traffic to XRv4's loopback using a source of 10.9.2.9, which is directed to CSR6. To verify the asymmetry, CSR6 performs a lookup in its global FIB and routes the packet to XRv4 over the backdoor. XRv4 performs a lookup in its VRF-aware FIB, processes the local packet, and routes the reply directly to CSR2.

```
R6#show ip cef 192.104.14.14
192.104.14.14/32
  nexthop 192.6.104.14 GigabitEthernet2.204
```

```
RP/0/0/CPU0:XRv4#show cef vrf BGP ipv4 192.104.14.14
192.104.14.14/32, version 17, attached, receive
  Prefix Len 32

```

```
RP/0/0/CPU0:XRv4#show cef vrf BGP ipv4 10.9.2.9
10.0.0.0/8, version 4655, internal 0x5000001 0x0 (ptr 0xa1415674) [1], 0x0
(0x0), 0x0 (0x0)
  local adjacency 10.2.14.2
  Prefix Len 8, traffic index 0, precedence n/a, priority 3
  via 10.2.14.2, 2 dependencies, recursive [flags 0x6000]
  path-idx 0 NHID 0x0 [0xa1413674 0x0]
  next hop VRF - 'default', table - 0xe0000000
  next hop 10.2.14.2 via 10.2.14.2/32
```

CSR2's inbound policy-routing matches an ACL that only accounts for traffic sourced from 10.2.9.0/24. The routing entry we added earlier would cause the packet to loop until TTL expires, which is undesirable.

```
R2#show route-map RM_FROM_XRV4
route-map RM_FROM_XRV4, permit, sequence 10
  Match clauses:
    ip address (access-lists): ACL_RETURN_XRV4
  Set clauses:
    ip global next-hop 2.2.2.9
  Policy routing matches: 92 packets, 10840 bytes
```

```
R2#show access-lists ACL_RETURN_XRV4
Extended IP access list ACL_RETURN_XRV4
  10 permit ip any 10.2.9.0 0.0.0.255
```

```
R2#show ip cef vrf VIA_XRV4 10.9.2.0
0.0.0.0/0
  nexthop 10.2.14.14 GigabitEthernet2.524
```

Because this route-map clause manually sets the correct next-hop, we don't have to worry about changing the VIA_XRV4 routing table. Instead, we can simply invoke the pre-existing ACL_RETURN_XRV4 access-list in the same route-map entry. This will use Boolean OR logic, so that traffic destinations matching either list can be forwarding to 2.2.2.9. We are effectively extending the match logic in the route-map to account for both 10.2.9.0/24 and 10.9.2.0/24.

```
! CSR2
route-map RM_FROM_XRV4 permit 10
  match ip address ACL_RETURN_XRV4 ACL_RETURN_CSR6

R2#show route-map RM_FROM_XRV4
route-map RM_FROM_XRV4, permit, sequence 10
  Match clauses:
    ip address (access-lists): ACL_RETURN_XRV4 ACL_RETURN_CSR6
  Set clauses:
    ip global next-hop 2.2.2.9
  Policy routing matches: 95 packets, 11194 bytes
```

Next, we verify that CSR9 has reachability to all remote loopbacks from all valid sources. We can use a nested set of for loops to accomplish this. After enumerating all the possibilities for the destination, we nest another loop to iterate over the sources. The result is X * Y (8 total) verifications. The output is not shown, but it was successful for all ping targets.

```
! CSR9
tclsh
foreach x {
192.104.5.5
192.104.6.6
192.104.13.13
192.104.14.14
} { foreach y {
10.2.9.9
10.9.2.9
} { ping $x source $y repeat 3 timeout 1 } }
```

Regarding IPv6, XE only supports route-export from VRF to global. Importing from global to VRF does not appear supported in this code release. Only being able to go one-way seems awkward and incapable.

```
R6(config-vrf-af)#export ?
  ipv6  Address family based VRF export
  map   Route-map based VRF export

R6(config-vrf-af)#import ?
  map   Route-map based VRF import
```

We will test it briefly just to see the routes populated in the IPv6 global table, but nothing more. We will create an IPv6 prefix-list just to match the host routes inside of VRF BGP. We also need to include dummy RTs for this to work properly.

```
! CSR6
ipv6 prefix-list PL_HOST_ROUTES_V6 seq 5 permit ::/0 ge 128

route-map RM_VRF_TO_GLOBAL_V6 permit 10
 match ipv6 address prefix-list PL_HOST_ROUTES_V6

vrf definition BGP
 address-family ipv6
  export ipv6 unicast map RM_VRF_TO_GLOBAL_V6
  route-target export 1:1
  route-target import 1:1
```

As expected, we see all 4 loopbacks within the global table, including the non-best-paths seen by BGP. All of the BGP candidate routes are imported which is consistent with the IPv4 behavior. The VPNv6 BGP table for that VRF shows that 4 prefixes were exported out of a maximum of 1000. This is the same default as IPv4 and serves as a safety mechanism.

```
R6#show bgp ipv6 unicast | begin Network
      Network          Next Hop          Metric LocPrf Weight Path
* i  ::192:104:5:5/128

*>
      FD00:192:4:104::4
                                0 214 214 ?
```

```
R6#show bgp vpnv6 unicast vrf BGP | include t_Map
Export Map: RM_VRF_TO_GLOBAL_V6, Address-Family: IPv6 Unicast, Pfx
Count/Limit: 4/1000
```

The global routing table now shows these routes as BGP routes. For the connected loopback, we can see the % symbol is used to indicate that the interface is in a different VRF.

```
R6#show ipv6 route bgp | begin ^B
B   ::192:104:5:5/128 [20/0]
    via FE80::4, GigabitEthernet2.104
B   ::192:104:6:6/128 [20/0]
    via Loopback104%BGP, directly connected
B   ::192:104:13:13/128 [20/0]
    via FE80::4, GigabitEthernet2.104
B   ::192:104:14:14/128 [20/0]
    via FE80::4, GigabitEthernet2.104
```

An interesting note is that the VRF table selects XRv4 as the best-path to XRv4's loopback, which makes sense given the shorter AS path length. The global table selects CSR4 as the next-hop for this route (seen above, also) because the next-hop is inaccessible.

```
R6#show bgp vpnv6 unicast vrf BGP ::192:104:14:14/128

  Extended Community: SoO:214:3 RT:1:1
  rx pathid: 0, tx pathid: 0x0
```

This doesn't make sense since both routes are connected to CSR6 and are in the VRF; either both should be inaccessible or both should be accessible. Neither one was imported into the global table. The only difference I can see is that the valid route puts the next-hop's LL address into parenthesis.

```
R6#show ipv6 route FD00:192:4:104::
% Route not found
```

```
R6#show ipv6 route FD00:192:6:104::
% Route not found
```

Adjusting the next-hop inbound to include LL addresses does not solve the problem. The LL address of FE80::14 is still absent from the iBGP route.

```
! CSR6
route-map RM_IPV6_NHOP_ADJUST permit 10
  set ipv6 next-hop FD00:192:6:104::14 FE80::14

router bgp 104
  address-family ipv6 vrf BGP
    neighbor FD00:192:6:104::14 route-map RM_IPV6_NHOP_ADJUST in

R6#show bgp vpnv6 unicast vrf BGP ::192:104:14:14/128 | include via vrf
  FD00:192:6:104::14 (via vrf BGP) from FD00:192:6:104::14 (14.14.14.14)
  FD00:192:4:104::4 (FE80::4) (via vrf BGP) from FD00:192:4:104::4
(214.0.0.4)
```

A last-ditch effort involves leaking that connected /64 route into the VRF to satisfy the route recursion. This actually does solve the problem, but is kind of a hack.

```
! CSR6
ipv6 prefix-list PL_HOST_ROUTES_V6 seq 10 permit FD00:192:6:104::/64

R6#show ipv6 route bgp | begin ^B
B  ::192:104:5:5/128 [20/0]
    via FE80::4, GigabitEthernet2.104
B  ::192:104:6:6/128 [20/0]
    via Loopback104%BGP, directly connected
B  ::192:104:13:13/128 [20/0]
    via FE80::4, GigabitEthernet2.104

    via FD00:192:6:104::14%BGP, GigabitEthernet2.104%BGP
B  FD00:192:6:104::/64 [20/0]
```

via GigabitEthernet2.204%BGP, directly connected

The feature appears more stable on XR. We will leak the IPv6 VPN loopbacks into the global table, re-using the RPL from earlier by feeding it a new prefix set. We also have to initialize the IPv6 unicast AFI under BGP.

```
! Xrv4
vrf BGP
  address-family ipv6 unicast
    export to default-vrf route-policy RPL_LEAK(PS_VRF_TO_GLOBAL_V6)

prefix-set PS_VRF_TO_GLOBAL_V6
  ::/0 ge 128
end-set

router bgp 104
  address-family ipv6 unicast
```

Once the IPv6 unicast AFI is finishing initializing and importing the routes, we can see them in the global table. All of the next-hops are reachable, so we don't have the same problem on XR as we did on XE. We can see all four of the routes have the correct next-hops, all have valid best-paths, and all were imported from the source VRF BGP.

```
RP/0/0/CPU0:XRv4#show bgp ipv6 unicast imported-routes vrf BGP | begin
Network
```

Network	Neighbor	Route Distinguisher	Source VRF
*> ::192:104:5:5/128	fd00:192:3:104::3	214:104	BGP
*>i ::192:104:6:6/128	fd00:192:6:104::6	214:104	BGP
*> ::192:104:13:13/128	fd00:192:3:104::3	214:104	BGP
*> ::192:104:14:14/128	::	214:104	BGP

The routing table displays the expected information as well. Remote routes, like CSR5's loopback, are reachable via the PE (CSR3). The "local site" route of CSR6's loopback is reachable via the backdoor link.

```
RP/0/0/CPU0:XRv4#show route ipv6 unicast bgp
B    ::192:104:5:5/128
      [20/0] via fe80::3 (nexthop in vrf BGP), 00:00:44,
GigabitEthernet0/0/0/0.104
B    ::192:104:6:6/128
      [200/0] via fd00:192:6:104::6 (nexthop in vrf BGP), 00:00:44
B    ::192:104:13:13/128
```

```

[20/0] via fe80::3 (nexthop in vrf BGP), 00:00:44,
GigabitEthernet0/0/0/0.104
B    ::192:104:14:14/128 is directly connected,
      00:00:44, Loopback104 (nexthop in vrf BGP)

```

We can also import global routes into a VRF on XR for IPv6. Using the connected route on XRv4's interface to CSR2, we re-use the RPL using a new prefix-set to import the route from global to VRF BGP. We need to ensure this route is advertised into BGP, or else the import will not work.

```

! XRv4
prefix-set PS_GLOBAL_TO_VRF_V6
  2001::/16 le 96
end-set

vrf BGP
  address-family ipv6 unicast
    import from default-vrf route-policy RPL_LEAK(PS_GLOBAL_TO_VRF_V6)

router bgp 104
  address-family ipv6 unicast
    network 2001:dead:beef:cafe::/64

```

First, we confirm the route was successfully advertised into the IPv6 unicast global BGP table via the network statement. Then, we confirm it was imported into the VPNv6 BGP table for VRF BGP using the import route-policy. Just like with IPv4, BGP calls this route an “extranet”, which has eBGP characteristics, except with an AS path length of 0 (route is local). The source VRF is identified as being the default table (global) with no RD.

```

RP/0/0/CPU0:XRv4#show bgp ipv6 unicast 2001::/16 longer-prefixes | begin
Network
  Network          Next Hop          Metric LocPrf Weight Path
*> 2001:dead:beef:cafe::/64
      ::              0              32768 i

RP/0/0/CPU0:XRv4#show bgp vpnv6 unicast vrf BGP 2001:dead:beef:cafe::/64 |
beg$
  Local
  :: from 0.0.0.0 (14.14.14.14)
    Origin IGP, metric 0, localpref 100, weight 32768, valid, extranet,

    Received Path ID 0, Local Path ID 1, version 139
    Source VRF: default, Source Route Distinguisher: 0:0:0

```

From routers across the VPN, there is nothing special about this route, and it looks like a normal BGP route within the MPLS L3VPN. We can verify reachability from XRv4 to the other loopbacks using this route to ensure the import/export successfully achieves full reachability.

```

38.5 L3VPN import/export maps

Both XE and XR support the ability to apply additional constraints to restrict VPN membership beyond a simple RT import/export policy. This allows the routers to advertise certain routes with additional exported route-targets, or to filter inbound routes more aggressively even if they match the RT-import configured. Essentially, it is a per-prefix granularity tool to refine VPN membership. For this test, we will use CSR7 and XRv2 as the PEs to exchange routes between VRF BGP and VRF TOP. First, we verify the existing RT import/export policies on both routers. CSR7 has an asymmetric policy where it imports and exports routes with different RTs. XRv2 uses RT:214:104 for both directions.

```

R7#show vrf detail TOP | include Address|VPN|RT
VRF TOP (VRF Id = 1); default RD 214:7; default VPNID <not set>
Address family ipv4 unicast (Table ID = 0x1):
  Export VPN route-target communities
  RT:214:7
  Import VPN route-target communities
  RT:214:8
Address family ipv6 unicast (Table ID = 0x1E000001):
  Export VPN route-target communities
  RT:214:7
  Import VPN route-target communities
  RT:214:8
Address family ipv4 multicast not active

```

```
RP/0/0/CPU0:XRv2#show vrf BGP
```

VRF	RD	RT	AFI	SAFI
BGP	214:104			
		import 214:104	IPV4	Unicast
		export 214:104	IPV4	Unicast
		import 214:104	IPV6	Unicast
		export 214:104	IPV6	Unicast

The first goal will be to get all IPv4 host routes from XRv2 VRF BGP into CSR7 VRF TOP without configuring CSR7. If we didn't have the host route restriction, we could just add another export RT to XRv2 with value RT:214:8. That configuration is shown below, but is uncommitted, since it is incorrect.

```
! XRv2 (not committed, incorrect)
vrf BGP
  address-family ipv4 unicast
    export route-target
      214:8
```

We know that CSR7 is already importing RT:214:8, and it would work. However, we need to be more granular and only attach RT:214:8 to host routes inside the VPN. Non-matching routes will not have RT:214:8 applied, which means CSR7 will not import them into VRF TOP. Using RPL, we can construct a flexible policy to do this. We already have a prefix-set matching IPv4 host routes from earlier, so we can reuse that. The policy adds (does not replace) another RT to the extended community list and simply passes other routes. The "passed" routes will only have the "normal" export RTs defined under the VRF.

```
! XRv2
vrf BGP
  address-family ipv4 unicast
    export route-policy RPL_IF_MATCH_SET_RT(PS_HOST_ROUTES, RT_214_8)

extcommunity-set rt RT_214_8
  214:8
end-set

route-policy RPL_IF_MATCH_SET_RT($PS, $RT)
  if destination in $PS then
    set extcommunity rt $RT additive
  else
    pass
  endif
end-policy
```

After applying this policy, we confirm that it is working locally. XRv2 learns multiple routes from CSR5, and two are shown below. The PE-CE link does not have the new RT but the host route does, implying that the policy worked.

```
RP/0/0/CPU0:XRv2#show bgp vpnv4 unicast vrf BGP 192.12.104.0/24 | include
Extend
```

```
Extended community: SoO:214:513 RT:214:104
```

```
RP/0/0/CPU0:XRv2#show bgp vpnv4 unicast vrf BGP 192.104.5.5/32 | include
Extend
```

```
Extended community: SoO:214:513 RT:214:8 RT:214:104
```

Of greater importance is verifying that these routes were imported on CSR7. We can use a regex to filter based on originating AS 104 to ensure only the host routes were allowed. Since XRv2 only originated one host route, it imposed RT:214:8 on that single route only. The route contains all information we would expect to see, including the new RT, MPLS label, and other components needed for reachability.

```
R7#show bgp vpnv4 unicast vrf TOP quote-regex "104$" | begin Network
Network           Next Hop           Metric LocPrf Weight Path
Route Distinguisher: 214:7 (default for vrf TOP)
*>i 192.104.5.5/32  214.0.0.12          0      100      0 104 ?
```

```
R7#show bgp vpnv4 unicast vrf TOP 192.104.5.5/32

      mpls labels in/out nolaabel/92014
      rx pathid: 0, tx pathid: 0x0
```

At this point, we will not have reachability since XRv2 is not importing RT:214:7, which is exported by CSR7. At this point, we can either export RT:214:104 on CSR7 or import RT:214:7 on XRv2. The two approaches have different consequences. Exporting RT:214:104 on CSR7 means that all 4 of the PEs will be importing those routes, since all of them are importing RT:214:104 into VRF BGP. Importing RT:214:7 on XRv2 means that only XRv2 (not counting CSR8) will import those routes, which is probably cleaner. However, we add the additional requirement that XRv2 should not import all of the routes from CSR7 since there are several. We will attempt to match /26 routes with RT:214:7 set. It is important that the RPL test for RT:214:7 in the match statement or else the /26 filter would apply to all imported routes. Our requirement is to permit /26 prefixes with RT:214:7 while not applying this strict filter to other imported routes.

```
! XRv2
vrf BGP
  address-family ipv4 unicast
    import route-policy RPL_IF_MATCH_PASS(PS_LENGTH_26, RT_214_7)
```

```

extcommunity-set rt RT_214_7
    214:7
end-set

prefix-set PS_LENGTH_26
    0.0.0.0/0 ge 26 le 26
end-set

route-policy RPL_IF_MATCH_PASS($PS, $RT)
    if destination in $PS and extcommunity rt matches-every $RT then
        pass
    elseif extcommunity rt matches-every $RT then
        drop
    else
        pass
    endif
end-policy

```

After applying this configuration, XRv2 is not importing any routes from AS 88 into VRF BGP. Because XRv2 is a route-reflector, it already retains all the VPN routes, so we can verify that it is at least receiving them from CSR7 within RD:214:7 (RD, not RT). The RT of the route is RT:214:7 as expected. For some reason, the configuration did not work.

```

RP/0/0/CPU0:XRv2#show bgp vpnv4 unicast vrf BGP regexp 88$
[no output]

```

```

RP/0/0/CPU0:XRv2#show bgp vpnv4 unicast rd 214:7 88.125.160.128/26
[snip]
88, (Received from a RR-client)

    Origin IGP, metric 0, localpref 100, valid, internal, best, group-best,
import-candidate, not-in-vrf
    Received Path ID 0, Local Path ID 1, version 896
    Extended community: RT:214:7

```

The reason for this issue is in the order of operations. The import-map is processed only after the routes enter the VRF, and they enter the VRF via the “import route-target” command. Therefore, we must specify the RT manually in the VRF, then use the RPL to filter the routes further. This is also like the export-map which is processed after “export route-target”, which is why we must be careful not to overwrite RT values. We will correct our configuration below. The RPL is still correct in its three-stage logic: pass if RT:214:7 and /26, drop if RT:214:7 (non /26 prefixes from AS 88), pass otherwise (for unrelated imports).

```

! XRv2
vrf BGP

```

```
address-family ipv4 unicast
import route-target 214:7
```

Now, we can see the /26 routes from AS 88 in VRF BGP as expected. The RPL filtered all of the non /26 routes during the import process, but only routes already matching RT:214:7 were candidates to be compared against that filter.

```
RP/0/0/CPU0:XRv2#show bgp vpnv4 unicast vrf BGP regexp 88$ | begin Network
      Network                Next Hop                Metric LocPrf Weight Path

*>i88.125.160.192/26          214.0.0.7                0      100      0 88 i
```

We quickly check the routes on CSR5 and CSR10 to ensure the ultimate endpoints can reach one another. Then, we confirm the data-plane is functional using ping. CSR10 has the route to CSR5's loopback, and CSR5 has the routes to CSR1's /26 prefixes. Notice that we achieved this new reachability without configuring CSR7 at all.

```
R10#show bgp ipv4 unicast quote-regexp "104$" | begin Network
      Network                Next Hop                Metric LocPrf Weight Path
*> 192.104.5.5/32            10.7.10.7                0      100      0 214 104 ?
```

```
R5#show bgp vpnv4 unicast vrf BGP quote-regexp "88$" | begin Network

```

We will examine the feature on XE as well, this time using IPv6 prefixes. Specifically, we will enable connectivity between XRv3's loopback and the /70's within AS 82 by only configuring CSR8. First, we will import XRv3's loopback into VRF BOTTOM using RT:214:104. We will do it incorrectly as we did on XR by trying to import the RT within the import-map; this is not supported on either platform.

```
! CSR8
ipv6 prefix-list PL_XRV13_LOOPBACK seq 5 permit ::192:104:13:13/128
ip extcommunity-list standard EXTCOML_RT_214_104 permit rt 214:104
```

```

route-map RM_VRF_IMPORT permit 10
  match extcommunity EXTCOML_RT_214_104
  match ipv6 address prefix-list PL_XRV13_LOOPBACK

vrf definition BOTTOM
  address-family ipv6
    import map RM_VRF_IMPORT

```

We can verify the configuration was successfully applied by checking the VRF details. BGP debugging reveals that the route is still rejected due to the import-RT policy not including RT:214:104. Even though the route-map clearly imports this RT, it is not accepted for VPN membership due to the order of operations. The import-map is only applied against routes already imported by the “route-target import” command.

```

R8#show vrf detail BOTTOM | begin v6
Address family ipv6 unicast (Table ID = 0x1E000001):
  Flags: 0x0
  Export VPN route-target communities
    RT:214:8
  Import VPN route-target communities
    RT:214:7 RT:214:103
  Import route-map: RM_VRF_IMPORT
  No global export route-map
  No export route-map
  VRF label distribution protocol: not configured
  VRF label allocation mode: vrf-conn-aggr (Label 8019)
Address family ipv4 multicast not active

```

```

R8#debug bgp vpnv6 unicast updates in
BGP(5): 214.0.0.3 rcvd [214:104]::192:104:13:13/128, label 91015 -- DENIED
due to: extended community not supported;

```

We can modify the configuration on CSR8 as we did on XRv2. We will remove the extcommunity-list containing the new RT and just import it the normal way. Then, we leave the filter in place to select the prefixes we want based on other attributes (other community values, prefix length, etc). This may create issues later when dealing with imports unrelated to RT:214:104, but we will continue anyway.

```

! CSR8
no ip extcommunity-list standard EXTCOML_RT_214_104 permit rt 214:104

route-map RM_VRF_IMPORT permit 10
  no match extcommunity EXTCOML_RT_214_104

vrf definition BOTTOM
  address-family ipv6
    route-target import 214:104

```

Now, we can see XRv3's loopback inside of the VRF table as expected. This means that the custom import was successful and that those other routes originating from AS 104 were filtered.

```
R8#show bgp vpnv6 unicast vrf BOTTOM quote-regexp "104$" | begin Network
      Network          Next Hop          Metric LocPrf Weight Path
Route Distinguisher: 214:8 (default for vrf BOTTOM)
*>i  ::192:104:13:13/128
                                     ::FFFF:214.0.0.11
                                           0      100      0 104 ?
```

There is no reachability from AS 82 to XRv3's loopback since XRv1 is not importing RT:214:8, which CSR8 is exporting. We will configure CSR8 to export RT:214:104 so that XRv1 can import it. The danger here is that all PEs will import these routes, but will not have bidirectional connectivity since CSR8 only imported XRv3's loopback. In a real design, another RT would be used to exchange these routes, say RT:214:500, which XRv1 can import and CSR8 can append to the /70s it wants XRv1 to see. We will also take this opportunity to prove the order of operations when using export maps by intentionally forgetting the "additive" keyword.

```
! CSR8
ipv6 prefix-list PL_LENGTH_70 seq 5 permit ::/0 ge 70 le 70

route-map RM_VRF_EXPORT permit 10
 match ipv6 address prefix-list PL_LENGTH_70
 set extcommunity rt 214:104

vrf definition BOTTOM
 address-family ipv6
  export map RM_VRF_EXPORT
```

After applying this export, BGP needs to be cleared in order for the RT changes to have effect. First, we can validate that the configuration was successful by checking the VRF details.

```
R8#show vrf detail BOTTOM | begin v6
Address family ipv6 unicast (Table ID = 0x1E000001):
  Flags: 0x0
  Export VPN route-target communities
    RT:214:8
  Import VPN route-target communities
    RT:214:104
  Import route-map: RM_VRF_IMPORT
  No global export route-map
  Export route-map: RM_VRF_EXPORT
  VRF label distribution protocol: not configured
  VRF label allocation mode: vrf-conn-aggr (Label 8019)
Address family ipv4 multicast not active
```

Looking at the details of a /70 route, we can see the new RT:214:104 was applied, but the originally exported RT:214:8 was erased. This will allow all of the VRF BGP PE's to import this route, but CSR7 can no longer. This proves that the export-map happens after the "route-target export" command, overwriting whatever RTs were exported.

```

```

Debugging on CSR7 reveals that the routes from AS 82 are now being denied as they no longer carry RT:214:8 which CSR7 expects to import. Other routes (the non /70 prefixes) are still imported to CSR7 since their RT values were never adjusted. The /72s are still successfully installed, for example.

To fix this, we can correct the route-map to use the “additive” keyword when setting a new RT. This is the most straightforward and logical way to solve the problem and is something we used on XRv2 earlier. However, I will solve it another way; perhaps we are not allowed to use the “additive” keyword. We can remove the generalized RT export from the VRF; we will apply the general export RT:214:8 to IPv4 only so that AFI is unaffected. Removing it from the top-level VRF configuration means the IPv6 AFI cannot inherit it. We will extend the IPv6 export route-map to include a default match-any clause that sets RT:214:8 on everything not previously matched. The /70s matched in the first clause are assigned both RT:214:104 and RT:214:8, ultimately receiving all the RTs they need. Non /70 routes only receive RT:214:8 as expected. We could have solved this by not having a second route-map clause and having left the “inheritance” RT inside the VRF as well, which would have been simpler.

```
! CSR8
vrf definition BOTTOM
  no route-target export 214:8
  address-family ipv4
    route-target export 214:8

route-map RM_VRF_EXPORT permit 10
  match ipv6 address prefix-list PL_LENGTH_70
  set extcommunity rt 214:8 214:104
route-map RM_VRF_EXPORT permit 20
  set extcommunity rt 214:8
```

We can verify this on CSR8 by looking at a /70 and /71, noticing that the /70 gets both RT values. One of the routes is eBGP learned while the other is a local aggregate; both are subject to the export-map adjustments.

```

```

Next, let's verify that CSR7 is able to import these routes. We don't need to see the route details; we can safely assume that so long as BGP selected a best-path, the routes are valid. The data-plane is expected to work since it worked for all other prefixes earlier.

```
R7#show bgp vpnv6 unicast vrf TOP quote-regexp "82$" | include /70
*>i 2BAD:82:125:160:400::/70
*>i 2BAD:82:125:160:800::/70
*>i 2BAD:82:125:160:C00::/70
```

There is one other issue with the RT inheritance on CSR8, and this is the result of an earlier change. When configuring RT import values at the top level and the AFI level, the AFI level takes precedence. Given this configuration, only RT:214:104 is imported into the IPv6 AFI. The RTs of 214:7 and 214:103 are no longer considered for import into the IPv6 AFI.

```
! CSR8
vrf definition BOTTOM
```

```
rd 214:8
route-target import 214:7
route-target import 214:103
address-family ipv6
    route-target import 214:104
```

```
R8#show vrf detail BOTTOM | begin v6
Address family ipv6 unicast (Table ID = 0x1E000001):
  Flags: 0x0
  No Export VPN route-target communities
  Import VPN route-target communities
    RT:214:104
  Import route-map: RM_VRF_IMPORT
  No global export route-map
  Export route-map: RM_VRF_EXPORT
  VRF label distribution protocol: not configured
  VRF label allocation mode: vrf-conn-aggr (Label 8019)
Address family ipv4 multicast not active
```

To correct this, we need to add RT:213:103 (for IS-IS testing completed earlier) and RT:214:7 (to import routes from CSR7) under the IPv6 AFI. Because the IPv4 AFI has not defined explicit RT-import policies, it can still inherit from the top-level configuration, so we won't delete those. We can tell this new configuration is working by looking at the VRF details.

```
! CSR8
vrf definition BOTTOM
rd 214:8
! route-target import 214:7
! route-target import 214:103
address-family ipv6
    route-target import 214:104
    route-target import 214:7
    route-target import 214:103
```

```
R8#show vrf detail BOTTOM | begin v6
Address family ipv6 unicast (Table ID = 0x1E000001):
  Flags: 0x0
  No Export VPN route-target communities
  Import VPN route-target communities
    RT:214:104          RT:214:7          RT:214:103
  Import route-map: RM_VRF_IMPORT
  No global export route-map
  Export route-map: RM_VRF_EXPORT
  VRF label distribution protocol: not configured
  VRF label allocation mode: vrf-conn-aggr (Label 8019)
Address family ipv4 multicast not active
```

Even after this, we still don't have the AS 88 routes in CSR8's VPN table anymore. The import-map we applied earlier is the problem; it indiscriminately drops anything that is not XRv3's loopback. We can tell by looking at the routes in the VPN table that are not from AS 82; there is only one. This is somewhat similar to the RPL on XRv2 where we needed to use multiple conditional matches to achieve the desired result.

```
R8#show bgp vpnv6 unicast vrf BOTTOM quote-regexp "[^82]" | begin Network
      Network          Next Hop          Metric LocPrf Weight Path
Route Distinguisher: 214:8 (default for vrf BOTTOM)
*>i ::192:104:13:13/128
      ::FFFF:214.0.0.11
                                0      100      0 104 ?
```

Ideally, we need to allow all routes from AS 88. We have successfully imported RT:214:7 but the routes were filtered by the second-stage import-map. We can safely permit all routes from AS 88 because this route-map is only evaluated after the RT import process.

```
! CSR8
ip as-path access-list 88 permit 88$
```

```
route-map RM_VRF_IMPORT permit 10
  match ipv6 address prefix-list PL_XRV13_LOOPBACK
route-map RM_VRF_IMPORT permit 20
  match as-path 88
```

```
R8#show bgp vpnv6 unicast vrf BOTTOM quote-regexp "88$" | begin Network
      Network          Next Hop          Metric LocPrf Weight Path
Route Distinguisher: 214:8 (default for vrf BOTTOM)
*>i 2BAD:88:125:160::/72
      ::FFFF:214.0.0.7
                                0      100      0 88 i
*>i 2BAD:88:125:160:100::/72
      ::FFFF:214.0.0.7
                                0      100      0 88 i
[snip]
```

Now that routing has been verified, we quickly test IPv6 reachability between AS 88 and XRv3's loopback. This proves that the "extranet" configuration was successful.

[snip]
Success rate is 100 percent (5/5), round-trip min/avg/max = 6/6/7 ms
```

This section introduced many advanced L3VPN and VRF techniques. In summary:

1. Top-level VRF configuration of RTs in XE is convenient but confusing. XR doesn't even support it. Policies configured there are inherited to child AFIs only if the child AFIs don't have policies of their own. The inheritance is not additive and is overridden by the child policy as those are more specific. I recommend to only configure RTs at the AFI level for clarity and consistency with XR.
2. Import/export maps are processed after the import/export RT process, respectively. You cannot use the import-map to match RTs for import. The import-map applies to routes already passing the import-RT check and serves as a second-stage filter for additional granularity. This route-map/RPL has an implicit-deny at the end; it will reject non-matching routes from VRF import.
3. Export-map RT application will overwrite RTs written by "route-target export" unless the "additive" keyword is used. Prefixes not permitted by the export-map are not denied, but they are unmodified; they will have the normal export RTs configured in the VRF and nothing else. This can be considered an "implicit-pass" at the end of the route-map/RPL. This feature isn't meant for denying routes, only adjusting exported RTs.

38.6 Half-Duplex VRF (HDVRF)

The half-duplex VRF (HDVRF) feature is a minor option within the scope of L3VPN. Integrating this with the existing large-scale VRF lab previously would have been difficult, so a small lab has been developed specifically to test this feature. An HDVRF effectively defines two VRFs per interface: one upstream and one downstream. Like an isolated private VLAN, a single downstream VRF can service many customers but ensure they do not have direct connectivity across the local PE. Instead, traffic can hairpin across the network; although seemingly inefficient, this might be valuable for security reasons. Perhaps there is a centralized security checkpoint consisting of firewalls and intrusion prevention systems that inspects all spoke-to-spoke traffic on the network. HDVRF simplifies configuration on the local PE since two VRFs, the upstream and downstream VRFs, can service an unlimited number of customers without leaking traffic laterally. The feature is not currently supported on XR platforms or for IPv6 in general. Below is a basic L3VPN network a corporate headquarters site whereby XRv2 allows traffic to hairpin between spokes. The Internet peering point is access-only and spokes cannot use CSR10 for hairpinning traffic between one another. The core runs basic OSPFv2, BGP VPNv4, and LDP as shown below.

Before beginning, the parser returns an error when trying to configure HDVRF with IPv6. The parser tells you the VRF assignment is simply ignored. To avoid any unforeseen consequences of this unsupported configuration, the IPv6 AFI has been removed from all VRFs. There is no 6VPE in this lab, either.

```
R5(config-subif)#vrf forwarding UP downstream DOWN
% VRF forwarding ignored for IPv6 on HDVRF interface GigabitEthernet2.556
```

Before configuring the VRFs, we will perform a quick check of the existing IGP, LDP, and BGP infrastructure; the configurations are very basic and not shown for brevity. CSR5 sees 5 routers in the area with no DRs as all links are point-to-point. XRV1 and CSR9 each see 3 LDP neighbors which suggests all LDP sessions are up. XRV1 is the VPNv4 RR and has a valid BGP session to each PE.

```

CSR8 and XRv4 are basic L3VPN PE's with no fancy configuration. They use BGP to communicate with CSR10 and XRv2, respectively. The sessions are currently up and the PE's are learning routes from each CE eBGP peer. We can see the route counts: CSR8 learns one route while XRv4 learns several.

```
R8#show bgp vpnv4 unicast vrf CENTRAL summary | begin ^Neigh
Neighbor      V      AS MsgRcvd MsgSent   TblVer  InQ  OutQ  Up/Down  State/PfxRcd

```

With the basic network verification complete, we will configure the HDVRF feature on CSR5. CSR6, CSR7, and XRv3 are spoke sites that all require Internet and Intranet access without direct spoke-to-spoke access. Without considering HDVRF, there are two general solutions to this problem:

1. Create three VRFs, each of which imports the RTs exported by CSR8 and XRv4, and exports a “spoke RT” that those routers can import. Spokes will have no connectivity unless the spoke routes are leaked somewhere upstream.
2. Create one VRFs which imports the RTs exported by CSR8 and XRv4 and exports a “spoke RT” that those routers can import. Spokes will have direct connectivity across CSR5 unless some kind of data-plane filter is applied.

Neither of these solutions work well in our environment to meet the requirements stated earlier. The first solution scales poorly since each spoke needs its own VRF, and spoke-to-spoke traffic is not inherent without additional work. The second is efficient from a forwarding perspective but “insecure” since XRv2 is the central point for all network security services. HDVRF is a combination of these two methods. We create two VRFs on CSR5 to represent upstream and downstream flows. Before adjusting any of the RT policies, we will configure the basic VRFs and apply them to the PE-CE interfaces.

```

! CSR5
vrf definition DOWN
  rd 35:6713

```

```

address-family ipv4

vrf definition UP
  rd 35:100
  address-family ipv4

interface GigabitEthernet2.553
  encapsulation dot1Q 3553
  vrf forwarding UP downstream DOWN

interface GigabitEthernet2.556
  vrf forwarding UP downstream DOWN

interface GigabitEthernet2.557
  vrf forwarding UP downstream DOWN

```

When we verify this configuration, we see that the DOWN VRF has a special “D” flag next to each interface. This specifies that the particular VRF is a downstream VRF on that interface. The lack of any flag specifies that the VRF is an upstream VRF. Below, we can see both UP and DOWN VRFs applied to the same interfaces.

```

R5#show vrf

```

Name	Default RD	Protocols	Interfaces
DOWN	35:6713	ipv4	Gi2.556 [D] Gi2.557 [D] Gi2.553 [D]
UP	35:100	ipv4	Gi2.556 Gi2.557 Gi2.553

We will need to exchange routing information with these spokes. Before we can do that, we must determine in which VRF the connected PE-CE subnets exist. This will determine in which VRF we must configure the PE-CE routing protocol. We quickly look at the VRF UP and DOWN routing tables to see that the connected routes are in the DOWN VRF. If we tried to configure BGP in the UP VRF, for example, there would be no route to the eBGP peer and the session would never form.

```

R5#show ip route vrf UP connected | include ^C_
[no output]

R5#show ip route vrf DOWN connected | include ^C_
C      10.5.6.0/24 is directly connected, GigabitEthernet2.556
C      10.5.7.0/24 is directly connected, GigabitEthernet2.557
C      10.5.13.0/24 is directly connected, GigabitEthernet2.553

```

Next, we configure BGP to each spoke. The BGP configuration is basic; the only noteworthy comment is that these sessions are in the DOWN VRF since that VRF contains the connected PE-CE subnets. We

quickly verify that the configuration was successful by verifying that the BGP sessions are up (CE configurations not shown).

```
! CSR5
router bgp 35
  template peer-session IPV4_UCAST_DOWN
    remote-as 6713
    password SPOKE
    ttl-security hops 1

  address-family ipv4 vrf DOWN
    neighbor 10.5.6.6 inherit peer-session IPV4_UCAST_DOWN
    neighbor 10.5.7.7 inherit peer-session IPV4_UCAST_DOWN
    neighbor 10.5.13.13 inherit peer-session IPV4_UCAST_DOWN
```

```
R5#show bgp vpnv4 unicast vrf DOWN summary | begin ^Neigh
Neighbor      V      AS MsgRcvd MsgSent  TblVer  InQ  OutQ Up/Down  State/PfxRcd
10.5.6.6      4      6713    756    765     81    0    0 11:17:40    1
10.5.7.7      4      6713    752    763     81    0    0 11:17:33    1
10.5.13.13    4      6713     49     72     81    0    0 00:45:15    1
```

Incoming routes learned by the PE are placed into the downstream VRF. This makes sense because BGP was configured in VRF DOWN and the connected subnets also exist there. A quick check of CSR5's VRF DOWN routing table reveals these three eBGP routes, one from each spoke.

```
R5#show ip route vrf DOWN bgp | include ^B_
B      100.6.6.6 [20/0] via 10.5.6.6, 00:54:27
B      100.7.7.7 [20/0] via 10.5.7.7, 00:54:27
B      100.13.13.13 [20/0] via 10.5.13.13, 00:54:25
```

Ultimately, both the Internet and Intranet routers will need reachability to these subnets, just like a normal L3VPN. Since the routes only exist in VRF DOWN, we will export RT:35:6713 onto these prefixes so that CSR8 and XRv4 can import them. Both the export and import processes are shown below.

```
! CSR5
vrf definition DOWN
  address-family ipv4
    route-target export 35:6713
```

```
! CSR8
vrf definition INTERNET
  address-family ipv4
    route-target import 35:6713
```

```
! XRv4
vrf CENTRAL
  address-family ipv4 unicast
```

```
import route-target
35:6713
```

We don't expect to have bidirectional connectivity since the routing advertisement is only complete in one direction. We verify that both CSR10 and XRv2 learn these spoke routes via BGP. From the perspective of CSR8 and XRv4, this is a normal L3VPN with no advanced features; they continue to import and export RTs as usual. The CENTRAL and INTERNET VRFs on these routers need not be HDVRF-aware since the feature is local to CSR5.

```
R10#show bgp ipv4 unicast 100.0.0.0/8 longer-prefixes | begin Network
      Network      Next Hop      Metric LocPrf Weight Path
*> 100.6.6.6/32    10.8.10.8
*> 100.7.7.7/32    10.8.10.8
*> 100.13.13.13/32 10.8.10.8
                                0 35 6713 i
```

```
RP/0/0/CPU0:XRv2#show bgp ipv4 unicast 100.0.0.0/8 longer-prefixes | begin

*> 100.7.7.7/32    10.12.14.14
*> 100.13.13.13/32 10.12.14.14
                                0 35 6713 i
```

To complete the routing configuration, we introduce the half-duplex nature of the VRFs on CSR5.

Incoming traffic towards the PE will use the upstream VRF for its route lookup, which implies that VRF UP should be importing the remote L3VPN routes. In summary, VRF UP is importing upstream routes to control how clients route upstream. VRF DOWN is exporting downstream routes to control how upstream clients route back towards spokes. After importing the Internet and Intranet RTs into VRF UP on CSR5, we look at the VPNv4 routes across both VRFs. VRF UP has reachability to the Internet and Intranet sites, while VRF DOWN has reachability to the spokes. In a normal L3VPN configuration, one would think that these were entirely different topologies as reachability appears fragmented.

```
! CSR5
vrf definition UP
 address-family ipv4
   route-target import 35:8
   route-target import 35:14
```

```
R5#show bgp vpnv4 unicast all | begin Network
      Network      Next Hop      Metric LocPrf Weight Path
Route Distinguisher: 35:100 (default for vrf UP)
*>i 0.0.0.0        35.0.0.8
*>i 12.24.0.0/16    35.0.0.14
                                0 100 0 10 i
                                100 0 12 ?
Route Distinguisher: 35:6713 (default for vrf DOWN)
*> 100.6.6.6/32    10.5.6.6
*> 100.7.7.7/32    10.5.7.7
*> 100.13.13.13/32 10.5.13.13
                                0
                                0 6713 i
                                0 6713 i
                                0 6713 i
```

At present, the spokes have no ability to reach any remote destinations since they haven't learned any routes from CSR5; VRF DOWN is not importing anything so nothing can be advertised to the spokes. As a quick fix, we will configure a static route on CSR6 only to achieve reachability.

```
! CSR6
ip route 0.0.0.0 0.0.0.0 10.5.6.5
```

When CSR6 sends traffic to CSR5, the FIB lookup happens in VRF UP regardless of whether VRF DOWN has a route or not. Two MPLS labels are imposed: the top label is XRv1's label for CSR8's loopback (transport) and the bottom label is CSR8's label for CSR10's loopback (VPN).

```
R5#show ip cef vrf DOWN 10.10.10.10
0.0.0.0/0
no route
```

```
R5#show ip cef vrf UP 10.10.10.10
0.0.0.0/0
  nexthop 35.5.11.11 GigabitEthernet2.551 label 91005 8010
```

```
R5#show mpls ldp bindings 35.0.0.8 32 neighbor 35.0.0.11
lib entry: 35.0.0.8/32, rev 20
  remote binding: lsr: 35.0.0.11:0, label: 91005
```

```
R5#show bgp vpnv4 unicast vrf UP labels
Network          Next Hop          In label/Out label
Route Distinguisher: 35:100 (UP)
  0.0.0.0          35.0.0.8          nolabel/8010
  12.24.0.0/16     35.0.0.14         nolabel/94023
```

XRv1 performs PHP and exposes label 8010 to CSR8. CSR8 removes all labels and delivers to the traffic to the Internet destination of 10.10.10.10. Once the label stack is imposed by CSR5, there is nothing special in the forwarding-plane.

```
RP/0/0/CPU0:XRv1#show mpls forwarding labels 91005

005056A9F961005056A9FB1C81000DFC0800
VPN route: INTERNET
```

No output feature configured

Earlier, we confirmed that the Internet and Intranet sites already had ordinary L3VPN routes back to the spokes. When CSR10 replies, CSR8 imposes two labels in similar fashion to what CSR5 did above. Rather than trace the LSP from CSR8 to CSR5, we will skip to CSR5, which receives packets labeled 5004 after XRv1 performs PHP. CSR5 removes all labels and delivers to packets to CSR6 inside VRF DOWN. This makes sense because the VPN route originated inside VRF DOWN since there is where BGP was configured. It is also the VRF in which the connected next-hop resides.

```
R8#show ip cef vrf INTERNET 100.6.6.6/32
100.6.6.6/32
  nexthop 35.8.11.11 GigabitEthernet2.581 label 91000 5004
```

```
R5#show mpls forwarding-table labels 5004 detail
Local      Outgoing  Prefix          Bytes Label  Outgoing  Next Hop
Label      Label     or Tunnel Id    Switched     interface
5004       No Label  100.6.6.6/32 [V] 590          Gi2.556     10.5.6.6
          MAC/Encaps=18/18, MRU=1504, Label Stack{}
          005056A9DE0D005056A9DC6381000DE40800
          VPN route: DOWN
          No output feature configured
```

To ensure connectivity is functional, we quickly ping from CSR6 to CSR10 before continuing.

```
R6#ping 10.10.10.10 source 100.6.6.6
Type escape sequence to abort.
Sending 5, 100-byte ICMP Echos to 10.10.10.10, timeout is 2 seconds:
Packet sent with a source address of 100.6.6.6
!!!!
Success rate is 100 percent (5/5), round-trip min/avg/max = 8/9/11 ms
```

Rather than configure static routes on all spokes, we can advertise the expected BGP routes to them. This is accomplished by importing CSR8's and XRv4's RT values on VRF DOWN. Since VRF DOWN is never used for upstream route lookups, having these in the PE's VRF DOWN routing table means nothing. Of greater importance is being able to advertise them down to the spokes. Note that this step is optional and is not required if the CEs have other upstream routing mechanisms (static, etc), as we just demonstrated on CSR6. We quickly check to ensure the routes were imported.

```
! CSR5
vrf definition DOWN
  address-family ipv4
    route-target import 35:8
    route-target import 35:14
```

```
R5#show bgp vpnv4 unicast vrf DOWN quote-regexp "^[^6]" | begin Network
Network          Next Hop          Metric LocPrf Weight Path
```

```

Route Distinguisher: 35:6713 (default for vrf DOWN)
*>i 0.0.0.0 35.0.0.8 0 100 0 10 i
*>i 12.24.0.0/16 35.0.0.14 100 0 12 ?

```

Looking at the details of the default route as an example, we see interesting output. CSR5 claims that the route was imported directly from VRF UP, not from VPNv4 BGP. This is odd because VRF UP is not exporting RT:35:8 yet the output seems to suggest that. In reality, this means that VRF DOWN is “borrowing” the route from the upstream routing VRF so that it can advertise it downwards.

```

R5#show bgp vpnv4 unicast vrf DOWN 0.0.0.0/0
BGP routing table entry for 35:6713:0.0.0.0/0, version 21
Paths: (1 available, best #1, table DOWN)
  Advertised to update-groups:
    3
  Refresh Epoch 1
  10, imported path from 35:100:0.0.0.0/0 (UP)
    35.0.0.8 (metric 3) (via default) from 35.0.0.11 (35.0.0.11)
      Origin IGP, metric 0, localpref 100, valid, internal, best
      Extended Community: RT:35:8
      Originator: 35.0.0.8, Cluster list: 35.0.0.11
      mpls labels in/out nlabel/8010
      rx pathid: 0, tx pathid: 0x0

```

As mentioned earlier, the local VRF DOWN RIB on CSR5 will now have these BGP routes, but they are irrelevant since they are not consulted when traffic is received from the CE. It is critical that the spokes learn these routes; we check CSR7 and XRv3 specifically. We also allowed the spokes to learn 12.24.0.0/16 since this was also “borrowed” from VRF UP to VRF DOWN. This is needed to route traffic towards the central services resources behind XRv2 in the case that the default route is not available.

```

R5#show ip route vrf DOWN bgp | include \[200
B* 0.0.0.0/0 [200/0] via 35.0.0.8, 00:04:50
B 12.24.0.0 [200/0] via 35.0.0.14, 00:04:50

R7#show ip route bgp | include ^B
B* 0.0.0.0/0 [20/0] via 10.5.7.5, 00:05:13
B 12.24.0.0 [20/0] via 10.5.7.5, 00:05:13

RP/0/0/CPU0:XRv3#show route bgp
B* 0.0.0.0/0 [20/0] via 10.5.13.5, 00:05:26
B 12.24.0.0/16 [20/0] via 10.5.13.5, 00:05:26

```

A quick set of tests confirms that this achieves connectivity between spokes and “hubs”. We don’t need to trace each LSP again since the forwarding plane is identical regardless of how the spokes learn their upstream routes.

```

R7#ping 10.10.10.10 source 100.7.7.7

```

```

[snip]
!!!!!!
Success rate is 100 percent (5/5), round-trip min/avg/max = 7/8/10 ms

R7#ping 12.24.48.1 source 100.7.7.7
[snip]
!!!!!!
Success rate is 100 percent (5/5), round-trip min/avg/max = 5/8/19 ms

RP/0/0/CPU0:XRv3#ping 10.10.10.10 source 100.13.13.13
[snip]
!!!!!!
Success rate is 100 percent (5/5), round-trip min/avg/max = 1/5/9 ms

RP/0/0/CPU0:XRv3#ping 12.24.48.1 source 100.13.13.13
[snip]
!!!!!!
Success rate is 100 percent (5/5), round-trip min/avg/max = 1/6/19 ms

```

Next, we will verify that hairpinning capability of HDVRF. Both CSR7 and XRv3 learn default routes from CSR5 inside the same VRF; under normal circumstances, traffic would be routed locally by CSR5 between these two endpoints. Since the routing lookup always happens in the upstream VRF, traffic will not be routed directly. In this example, we will trace the path from CSR7 to XRv3. When CSR7 sends packets to CSR5 for this destination it follows its default route.

```

R7#show ip cef 100.13.13.13
0.0.0.0/0
  nexthop 10.5.7.5 GigabitEthernet2.557

```

CSR5 performs a lookup in VRF UP and also finds that the default route is the best match. Traffic is tunneled inside MPLS all the way to CSR10, since that is where the default route was originated.

```

R5#show ip cef vrf UP 100.13.13.13
0.0.0.0/0
  nexthop 35.5.11.11 GigabitEthernet2.551 label 91005 8010

```

CSR10's longest-match for XRv3 is via CSR8 following a host route. Since CSR8 imported those downstream routes, but VRF UP didn't do it locally on CSR5, we have effectively created a large hairpin terminating on CSR10.

```

R10#show ip cef 100.13.13.13
100.13.13.13/32
  nexthop 10.8.10.8 GigabitEthernet2.580

```

CSR8 tunnels traffic inside MPLS back to CSR5 for forwards it to XRv3 inside VRF DOWN.

```
R8#show ip cef vrf INTERNET 100.13.13.13/32
```

```
100.13.13.13/32
```

```
nexthop 35.8.11.11 GigabitEthernet2.581 label 91000 5009
```

```
R5#show mpls forwarding-table labels 5009 detail
```

Local Label	Outgoing Label	Prefix or Tunnel Id	Bytes Switched	Outgoing interface	Next Hop
5009	No Label	100.13.13.13/32[V]	\		
			1888	Gi2.553	10.5.13.13

MAC/Encaps=18/18, MRU=1504, Label Stack{}

005056A9EA54005056A9DC6381000DE10800

VPN route: DOWN

No output feature configured

Using traceroute inside CSR7 reveals the entire path. CSR10 terminates the hairpin and is highlighted, but it is clear that traffic between spokes cannot be routed locally by CSR5.

```
R7#traceroute 100.13.13.13 source 100.7.7.7
```

```
Type escape sequence to abort.
```

```
Tracing the route to 100.13.13.13

```

This behavior is highly undesirable at present. Recall that CSR10 represents the Internet while XRv2 represents the central services site containing the security tools. Traffic is being hairpinned via an Internet router and totally bypassing the security features at XRv2. This is the result of VRF UP only having a default route to reach the spoke loopbacks. Instead, we must find a way to attract spoke-to-spoke traffic on XRv2. The simplest solution is a static null route advertised into BGP on XRv2. After configuring it, we verify that XRv1 (RR) learns this prefix.

```
! XRv2
router static
  address-family ipv4 unicast
    100.0.0.0/8 Null0

router bgp 12
  address-family ipv4 unicast
    network 100.0.0.0/8
```

```
RP/0/0/CPU0:XRv1#show bgp vpnv4 unicast rd 35:100 100.0.0.0/8 brief | begin
Network
  Network          Next Hop          Metric LocPrf Weight Path
Route Distinguisher: 35:100
*>i100.0.0.0/8      35.0.0.14          0      100      0 12 i
```

We quickly verify that all three spokes learn this prefix. Although the next-hop is the same as the default route, all of them will be following this new route to reach one another's loopbacks. I use three different verifications on the spokes for variety.

```
R6#show ip route 100.0.0.0 255.0.0.0
Routing entry for 100.0.0.0/8
  Known via "bgp 6713", distance 20, metric 0
  Tag 35, type external
  [snip]
```

```
R7#show ip cef 100.0.0.0/8
100.0.0.0/8
  nexthop 10.5.7.5 GigabitEthernet2.557
```

```
RP/0/0/CPU0:XRv3#show bgp ipv4 unicast 100.0.0.0/8 brief | begin Network
  Network          Next Hop          Metric LocPrf Weight Path
*> 100.0.0.0/8      10.5.13.5          0      35 12 i
```

Of paramount importance is the upstream VRF routing lookup on CSR5. Since the static null route on XRv2 is generic enough to cover all spoke loopbacks, yet more specific than the default route, it is preferred. Now traffic will hairpin through XRv2 as desired. Without performing a detailed verification, we know that label 94008 was allocated by XRv4; in this case, it represents XRv4's local VPN label for prefix 100.0.0.0/8.

```
R5#show ip cef vrf UP 100.6.6.6
100.0.0.0/8
  nexthop 35.5.9.9 GigabitEthernet2.559 label 9010 94008
```

```
R5#show ip cef vrf UP 100.7.7.7
100.0.0.0/8
  nexthop 35.5.9.9 GigabitEthernet2.559 label 9010 94008
```

```
R5#show ip cef vrf UP 100.13.13.13
100.0.0.0/8
  nexthop 35.5.9.9 GigabitEthernet2.559 label 9010 94008
```

Using traceroute from CSR7 again verifies this behavior. XRv2 is highlighted in the output below. At this point the HDVRF configuration is complete.

```
R7#traceroute 100.13.13.13 source 100.7.7.7
```

Type escape sequence to abort.

```

Earlier I briefly discussed the need for the spokes to learn the prefix 12.24.0.0/16 despite having a default route. To prove its value, we temporarily shut down CSR10's BGP session to CSR8 (not shown). Because CSR10 represents the Internet, we fully expect that the spokes will no longer have Internet reachability. They should, however, continue to have central services and "hairpin" services via XRv2. Checking CSR7, we can see that it retains both of these BGP routes but no longer learns a default dynamically. Without this route, even if the Internet was operational, the central services subnets would be unreachable. This is more of a basic L3VPN/routing issue than an HDVRF issue, but integrating an intelligent routing design with HDVRF is important.

```
R7#show ip route bgp | include ^B
B      12.24.0.0 [20/0] via 10.5.7.5, 00:34:33
B      100.0.0.0/8 [20/0] via 10.5.7.5, 00:10:44
```

CSR7 will not have Internet access since there is no route, but has full access to XRv2's services. We can tell by the long latency on the spoke-to-spoke ping that traffic is still being hairpinned via XRv2.

```
R7#show ip cef 10.10.10.10
0.0.0.0/0
  no route
```

```
R7#ping 100.13.13.13 source 100.7.7.7
[snip]
!!!!!!
Success rate is 100 percent (5/5), round-trip min/avg/max = 9/25/39 ms
```

```
R7#ping 12.24.48.1 source 100.7.7.7
[snip]
!!!!!!
Success rate is 100 percent (5/5), round-trip min/avg/max = 4/6/13 ms
```

38.7 BGP Local Convergence (VRF Local Protection)

This feature is difficult to classify by name since it is a combination of BGP, HA, L3VPN, and VRF features. It is designed to speed up BGP convergence on a local egress PE by protecting against a PE-CE link failure. Normally, when the PE-CE link fails, the eBGP session running over that link also fails. This will occur as a result of the “fast-external-falover” feature enabled by default if the link drops line-protocol. If the line-protocol doesn’t fail, such as would be the case in many Ethernet last-mile deployments, the BGP keepalive timer (or possibly BFD timer) must expire. Once this happens, the PE that suffered the link failure will withdraw the prefix from the BGP topology, which typically involves sending the MP_UNREACH_NLRI towards the RR. Assuming that BGP convergence is slow (that is to say, it takes time for the remote PEs to learn this update to select better paths), this can result in a significant amount of dropped traffic. Like TE-FRR in a way, VPN traffic destined for hosts behind the PE suffering the link failure will still be sent towards that PE. Here, the traffic would typically be blackholed while BGP was converging. With local protection, this egress PE will swap the VPN label to the VPN label of the backup egress PE and send the packet back into the MPLS core, effectively performing local repair until BGP converges. There are two key network design requirements in order to use this feature: the CE site must be multi-homed to at least two different PEs, and the primary egress PE must learn the backup PE’s VPN route. The second requirement can be achieved many ways: BGP additional-paths, diverse RDs, etc. The network diagram is shown below. CSR9 and CSR10 are in the same VPN and each one is multi-homed to two PEs.

Before beginning any advanced configuration, we verify the basic IGP, LDP, and BGP components. IS-IS level-2 is running on all nodes. A quick check of XRv1’s LSPDB shows 6 LSPs, each with the appropriate number of transit links. We also verify that each LSR advertises a single loopback into IGP. This quick check verifies the entire IGP topology quickly.

```

Since there are 6 LSRs in the network, we expect to see exactly 6 loopbacks. This is because each LSR is only allocating labels for host routes. Checking the core routers, we can see all LDP sessions are up with 6 IPv4-based labels exchanged between each set of peers.

```
RP/0/0/CPU0:XRv1#show mpls ldp neighbor brief
```

Peer	GR	NSR	Up Time	Discovery		Addresses		Labels	
				ipv4	ipv6	ipv4	ipv6	ipv4	ipv6

Next, we quickly verify the PE-CE routing. The local protection feature supports all protocols (including static routing) except for IS-IS within the IPv4 AFI, while IPv6 only supports BGP and static routing. To test as many combinations as possible, we will use a variety of PE-CE configurations. CSR9 will use BGP for both IPv4 and IPv6. The configuration is not shown since it is very basic, but we quickly verify that all sessions are functional from the perspective of CSR9. The only interesting configuration is that CSR9 is configured to always compared BGP RID; this ensures that CSR7 is always the primary next-hop since the eBGP oldest-route comparison is skipped.

```
! CSR9
router bgp 65009
  bgp bestpath compare-routerid
```

```
R9#show bgp ipv4 unicast summary | begin ^Neigh
```

Neighbor	V	AS	MsgRcvd	MsgSent	TblVer	InQ	OutQ	Up/Down	State/PfxRcd
10.7.9.7	4	212	29	31	31	0	0	00:20:45	1
10.8.9.8	4	212	43	46	31	0	0	00:31:29	1

```
R9#show bgp ipv6 unicast summary | begin ^Neigh
```

Neighbor	V	AS	MsgRcvd	MsgSent	TblVer	InQ	OutQ	Up/Down	State/PfxRcd
FD00:10:7:9::7	4	212	29	30	34	0	0	00:20:49	1
FD00:10:8:9::8	4	212	42	45	34	0	0	00:31:30	1

CSR10 will use OSPFv2 for IPv4 and static routing for IPv6. Both CSR5 and CSR6, as PEs, are never allowed to be the OSPF DR. If CSR10 fails, there is no reason for CSR5 and CSR6 to form a neighborhood as no routes need to be exchanged laterally. The IPv6 static routing is basic; note that the PE-CE LAN segment does not have any routable IPv6 addressing as it is not required. CSR10 uses different administrative distances for selection. CSR5 is always the primary next-hop as a result.

```
! CSR5 and CSR6
interface GigabitEthernet2.550
  ip ospf priority 0

ipv6 route vrf 910 910:10:10:10::10/128 GigabitEthernet2.550 FE80::10

! CSR10
ipv6 route ::/0 GigabitEthernet2.550 FE80::6 8
ipv6 route ::/0 GigabitEthernet2.550 FE80::5 4
```

Because the local protection feature requires the primary PE (CSR5 and CSR7 in this case) to learn the iBGP route via the backup PE, we used unique RDs on all PEs. BGP additional-paths would have been

appropriate also, but given XE's limited support for this feature within VPNv4/v6, unique RD was a simpler solution. We quickly check XRv1, the RR, to ensure that each PE is using a different RD. CSR9 and CSR10 contribute one route each as shown below. It is between these customer host addresses that we will test local protection. The RDs are highlighted for clarity; they key is that they are all different.

```
RP/0/0/CPU0:XRv1#show bgp vpnv4 unicast | begin Network

Route Distinguisher: 212:9107
*>i910:9:9:9::9/128  212.0.0.7      0     100    0 65009 ?
Route Distinguisher: 212:9108
*>i910:9:9:9::9/128  212.0.0.8      0     100    0 65009 ?
```

Because all of our PE-CE links are Ethernet-based, BGP's fast-external-fallover will not be valuable for detecting PE-CE link failures in a timely manner. We will use BFD to achieve less than 3 seconds detection time; the relatively slow timer is used given the CSR1000v's 100 kbps rate-limit. The BFD configuration is not discussed in detail since there is a dedicated chapter for it. For brevity, only the CE configurations are shown, but the BFD configurations are very similar on both ends of the PE-CE link.

```
! CSR9
router bgp 65009
 neighbor 10.7.9.7 fall-over bfd single-hop
 neighbor 10.8.9.8 fall-over bfd single-hop
 neighbor FD00:10:7:9::7 fall-over bfd single-hop
 neighbor FD00:10:8:9::8 fall-over bfd single-hop

interface GigabitEthernet2.579
 bfd interval 900 min_rx 900 multiplier 3

interface GigabitEthernet2.589
 bfd interval 900 min_rx 900 multiplier 3
```

```

! CSR10
interface GigabitEthernet2.550
  bfd interval 900 min_rx 900 multiplier 3

router ospf 910
  bfd all-interfaces

ipv6 route static bfd GigabitEthernet2.550 FE80::5
ipv6 route static bfd GigabitEthernet2.550 FE80::6

```

From the CE routers, we quickly verify that BFD is operational. Each CE should have 4 operational BFD sessions, two per AFI.

```
R9#show bfd neighbors
```

```
IPv4 Sessions
```

NeighAddr	LD/RD	RH/RS	State	Int
10.7.9.7	4097/4097	Up	Up	Gi2.579
10.8.9.8	4101/4097	Up	Up	Gi2.589

```
IPv6 Sessions
```

NeighAddr	LD/RD	RH/RS	State	Int
FD00:10:7:9::7	2/1	Up	Up	Gi2.579
FD00:10:8:9::8	1/2	Up	Up	Gi2.589

```
R10#show bfd neighbors
```

```
IPv4 Sessions
```

NeighAddr	LD/RD	RH/RS	State	Int
10.5.10.5	4097/4097	Up	Up	Gi2.550
10.5.10.6	4098/4097	Up	Up	Gi2.550

```
IPv6 Sessions
```

NeighAddr	LD/RD	RH/RS	State	Int
FE80::5	1/1	Up	Up	Gi2.550
FE80::6	2/1	Up	Up	Gi2.550

Quickly note that a positive side effect of removing CSR5 and CSR6 from the DR election is that they do not establish a BFD session with one another. OSPF only establishes BFD sessions to the DR and BDR as discussed in the BFD chapter.

```
R6#show bfd neighbors client ospf
```

```
IPv4 Sessions
```

NeighAddr	LD/RD	RH/RS	State	Int
10.5.10.10	4097/4098	Up	Up	Gi2.550

To test connectivity over the basic L3VPN, we use traceroute for brevity. Notice that CSR9 will always use CSR7 and CSR10 will always use CSR5, assuming CSR7 and CSR5 are up. These PEs are used for

ingress and egress by default; when comparing iBGP paths, the ingress PEs will select the egress PE with the lower BGP RID. This was done intentionally to converge the network deterministically and without advanced BGP best-path adjustments.

```
R10#traceroute 9.10.0.9 source 9.10.0.10
Type escape sequence to abort.
Tracing the route to 9.10.0.9
VRF info: (vrf in name/id, vrf out name/id)

 3 10.5.10.5 [MPLS: Label 5001 Exp 0] 10 msec 16 msec 13 msec
 4 10.5.10.10 22 msec 15 msec 10 msec
```

Before enabling local protection on the PEs, we will verify that the primary PEs (CSR5 and CSR7), at a minimum, have the iBGP paths from the backup PEs (CSR6 and CSR8). These do not need to be installed as “BGP backup paths” in the literal sense, but the routers need to have them. For variety, we check the local CE route on CSR5 using IPv4 and CSR7 using IPv6. The key word is “local”; this feature only provides FRR service for traffic egressing the core towards the customer. The primary paths are highlighted in yellow and the backup paths are in green. Notice that the label operations for the primary path is a basic imposition, while the backup path requires a VPN label swap. This makes sense since the backup PE changed the VPN next-hop, so BGP must perform a label swap to that backup PE’s local label. This label swapping intelligence has nothing to do with local protection as this is a fundamental component of BGP/MPLS interaction.

Before enabling local protection, we will break the link between CSR7 and CSR9 by changing the VLAN encapsulation (not shown). BGP update debugging is enabled on CSR7 for VPNv4 and VPNv6. Although CSR7 immediately installs the backup VPN route via CSR8, it withdraws its own route immediately to trigger a BGP convergence event. This is a good thing; there is no reason for CSR7 to continue advertising its ability to be an egress PE since this is no longer true.

```

R7#debug bgp vpnv4 unicast updates out

```

The fundamental issue is more subtle; CSR7 also immediately deallocates its local labels for those prefixes since it does not consider itself an ingress PE at all. This means that any traffic that may already be transiting the core will be dropped when CSR7 receives it, causing a short-term black hole. Until BGP converges around the failure, CSR7 will continue to drop packets received from the core. No matter how fast BGP converges, the packets that are already transiting the core would still be dropped.

```

  910:9:9:9::9/128  ::FFFF:212.0.0.8 nolabel/8015
  910:10:10:10::10/128
                        ::FFFF:212.0.0.6 nolabel/6020
                        ::FFFF:212.0.0.5 nolabel/5028
```

Local protection doesn't change the operation of BGP routing so much as it changes the label retention mechanism. Rather than immediately deallocating the local label for that prefix, the egress PE will retain it for 5 minutes, giving BGP plenty of time to converge. Packets that arrive on the egress PE will have their VPN label swapped per the LFIB, and any additional transport labels will be pushed as well. This behavior is similar to the PLR in TE-FRR and is only meant to be a temporary backup while BGP converges. The feature does not have any knobs and is simple to enable for IPv4 and IPv6; we enable it on all PEs. Technically, the feature only needs to be enabled on the primary PE, but we can enable it everywhere in case we decide to modify the BGP best-path selection algorithm later to prefer CSR6 or CSR8. The feature isn't explicitly supported in XR, but using BGP additional-paths, you could protect PE-CE links as seen in the "add-path" section. Once configured, we verify it by checking the VRF details.

! CSR5, CSR6, CSR7, and CSR8

```

vrf definition 910
  address-family ipv4
    protection local-prefixes
  address-family ipv6
    protection local-prefixes

R7#show vrf detail 910 | include ^Addr|Local
Address family ipv4 unicast (Table ID = 0x2):
  Local prefix protection enabled
Address family ipv6 unicast (Table ID = 0x1E000001):
  Local prefix protection enabled
Address family ipv4 multicast not active

```

Because BGP converges extremely fast in such a small network with so few prefixes, we need to slow it down. Using the “advertisement-interval” on each PE towards the RR, we can effectively limit how frequently the PEs can send successive updates/withdrawals across the network. We will introduce a long timer of 180 seconds (3 minutes) onto each PE. This means that the failure of a PE-CE link could take up to 3 minutes to converge, giving us time to verify that local protection works.

```

! CSR5, CSR6, CSR7, and CSR8
router bgp 212
  address-family vpnv4
    neighbor 212.0.0.11 advertisement-interval 180
  address-family vpnv6
    neighbor 212.0.0.11 advertisement-interval 180

```

After adjusting the advertisement interval, I quickly flap CSR9’s loopback. We can check the VPNv4/v6 update-groups on CSR7 to watch it count down as a result of seeing this instability. For the next ~3 minutes, CSR7 cannot send any kind of BGP updates to XRv2. We also ensure that CSR10’s VPN traffic is still egressing through CSR7. The VPN label allocated by CSR7 is 7003; this is the label we are trying to retain until BGP converges.

```

R7#show bgp vpnv4 unicast all update-group 212.0.0.11 | include Minimum
  Minimum time between advertisement runs is 180 seconds (expires in 176
seconds)

```

```

R10#traceroute 9.10.0.9 source 9.10.0.10
Type escape sequence to abort.

 4 10.7.9.9 19 msec 11 msec 10 msec

```

Moving quickly, we change the VLAN tag on CSR9 again to break the PE-CE link (not shown). Because CSR7 still has about 2 minutes remaining on its advertisement-interval, CSR7 cannot notify XRv1 about this change quite yet. Traffic from CSR10 will continue to flow towards CSR7 until the network is notified about the change. CSR7 knows that 232.0.0.8 (CSR8) is the correct next-hop for actually delivering the traffic. The difference is that its local label of 7003 is swapped to CSR8's local label of 8001 and sent towards 212.0.0.8. Without local protection, label 7003 would have been immediately deallocated.

```

```

Since CSR8 is multiple hops away, CSR7 must add additional MPLS encapsulation. The route to CSR8's loopback is learned via IGP, so an LDP label is used. In this case, label 92001 is pushed atop the stack to create {92001 8001}. Like a TE-FRR PLR, CSR7 adds additional labels to tunnel traffic towards the correct egress PE. This is why the primary PE must have the backup PE's route; if CSR7 didn't already have this iBGP path, local protection would not be useful.

```

 6 10.8.9.9 20 msec 10 msec 15 msec
```

At some point, CSR7's advertisement-interval will expire, which will trigger the much-needed BGP reconvergence event. CSR5 will be forced to select CSR8 as the best egress point; we can determine this by checking the VRF-aware FIB on CSR5. Label 8001 is at the bottom of the stack, which we already know is CSR8's VPNv4 label for CSR9's loopback. Traceroute from CSR10 also confirms this new LSP as there is no swapping of the VPN label anymore.

```
R5#show ip cef vrf 910 9.10.0.9/32
```

```

6 10.8.9.9 24 msec 10 msec 10 msec

```

Since the advertisement-interval was 2 minutes less than the time local protection retains local labels (always 5 minutes), we wait a bit longer before checking CSR7. After those 5 minutes expire, we can see that label 7003 has been totally deallocated as local protection is assumed to no longer be required.

```

R7#show bgp vpnv4 unicast vrf 910 9.10.0.9/32

```

We will quickly test the feature using IPv6 on the other side of the network. Because static routing is in use, we cannot flap CSR10's loopback to achieve the desired effect. Instead, we will quickly remove and re-add CSR5's static IPv6 route to CSR10's loopback. This has the same effect as it will trigger a BGP update from CSR5 and start the advertisement-interval. We check CSR5 to ensure the interval is counting down while also ensuring CSR9 still routes via CSR5 to reach CSR10. Note the original VPNv6 label value of 5032.

```

R5#show bgp vpnv6 unicast all update-group 212.0.0.11 | include Minimum
  Minimum time between advertisement runs is 180 seconds (expires in 178
seconds)

```

```

R9#traceroute ipv6
Target IPv6 address: 910:10:10:10::10
Source address: 910:9:9:9::9
[snip]
 1 FD00:10:7:9::7 3 msec 4 msec 5 msec
 2 ::FFFF:212.0.0.11 [MPLS: Labels 91000/5032 Exp 0] 7 msec 8 msec 9 msec

 4 910:10:10:10::10 [AS 212] 24 msec 14 msec 16 msec

```

Next, we break the PE-CE link between CSR5 and CSR10. Since this is a multi-access network, we must pay attention as to where we break the link. Doing so on the CE side would break everything, so we must break it on CSR5. We change the VLAN tag and wait about 3 seconds for BFD to detect the failure

(not shown). Once the link fails, we immediately check the VPNv6 BGP entry to ensure the local label value of 5032 has not been deallocated. CSR5 is performing the VPN label swap operation as expected.

```
R5#show bgp vpnv6 unicast vrf 910 910:10:10:10::10/128
BGP routing table entry for [212:9105]910:10:10:10::10/128, version 17
Paths: (1 available, best #1, table 910)

      Extended Community: RT:212:910
      Originator: 212.0.0.6, Cluster list: 212.0.0.11
      mpls labels in/out 5032/6027
      rx pathid: 0, tx pathid: 0x0
```

We can confirm this by checking the LFIB details. In the past, label 5032 was removed and the raw IPv6 traffic was delivered directly to CSR10. A broken PE-CE link requires CSR5 to swap the VPN label to 6027, CSR6's label for the same VPN route, then add a transport label to tunnel to packets across the core.

```
R5#show mpls forwarding-table labels 5032 detail
Local      Outgoing  Prefix          Bytes Label  Outgoing  Next Hop
Label      Label     or Tunnel Id    Switched     interface
5032       6027      910:10:10:10::10/128[V]  \
                                     1320          Gi2.551      212.5.11.11
MAC/Encaps=18/26, MRU=1496, Label Stack{91001 6027}
005056A92DC6005056A9DC6381000DDF8847 163790000178B000
VPN route: 910
No output feature configured
```

We can confirm the path using traceroute on CSR9 again. Notice that XRv1 is seen in the path twice; like TE-FRR, this is a valid design for short bursts of traffic and does not qualify as a “loop”. Also notice the label activity at CSR5; label 5032 is received and label stack {91001 6027} is sent back into the core as verified above. This behavior appears identical between IPv4 and IPv6.

```
R9#traceroute ipv6
Target IPv6 address: 910:10:10:10::10
Source address: 910:9:9:9::9
[snip]
 1 FD00:10:7:9::7 4 msec 4 msec 5 msec
 2 ::FFFF:212.0.0.11 [MPLS: Labels 91000/5032 Exp 0] 8 msec 8 msec 10 msec
 3 ::FFFF:212.5.11.5 [MPLS: Label 5032 Exp 0] 8 msec 22 msec 23 msec
 4 ::FFFF:212.0.0.11 [MPLS: Labels 91001/6027 Exp 0] 23 msec 22 msec 23 msec
 5 ::FFFF:212.6.11.6 [MPLS: Label 6027 Exp 0] 22 msec 27 msec 23 msec
 6 910:10:10:10::10 [AS 212] 23 msec 21 msec 15 msec
```

For a brief period of about 2 minutes, we can see that BGP has converged but local protection is still enabled on CSR5. This makes sense since 2 minutes is the difference between the advertisement interval and the local protection label retention timer. CSR9 now routes directly via CSR6, indicating BGP has converged correctly. CSR7 uses label 6027 directly at imposition rather than relying on CSR5 to swap it.

```
R9#traceroute ipv6
Target IPv6 address: 910:10:10:10::10
Source address: 910:9:9:9::9
[snip]
 1 FD00:10:7:9::7 3 msec 5 msec 4 msec
 2 ::FFFF:212.0.0.11 [MPLS: Labels 91001/6027 Exp 0] 113 msec 8 msec 8 msec
 3 ::FFFF:212.6.11.6 [MPLS: Label 6027 Exp 0] 18 msec 18 msec 17 msec
 4 910:10:10:10::10 [AS 212] 28 msec 22 msec 15 msec

R5#show bgp vpnv6 unicast vrf 910 labels
[snip]
 910:10:10:10::10/128
                        ::FFFF:212.0.0.6
                        5032/6027
```

Checking CSR5's label allocations shortly thereafter, label 5032 has been deallocated and traffic is now flowing solely through CSR6 as verified above.

```
R5#show bgp vpnv6 unicast vrf 910 labels
[snip]
 910:10:10:10::10/128
                        ::FFFF:212.0.0.6
                        nolabel/6027
```

Additional Reading – Reference configurations "vrf-local-prot"

39. Describe, implement, and troubleshoot Layer 2 failure detection

39.1 Link Aggregation Control Protocol (LACP)

LACP is a way to bond links together to create larger logical channels. This provides two key benefits: high availability and increased bandwidth. HA is inherent because if some number of links in the bundle fail, the remaining links serve as backups automatically. Bandwidth is increased by way of load-sharing across the links, and there are many algorithms to accomplish this. This lab uses two hardware ME-3400-24TS-A switches with ten links between them.

LACP is supported on ENI and NNI interfaces only, so the port-type is set to NNI for simplicity. The configuration of LACP is very simple; we specify the LACP bond number and the mode of operation. The channel-protocol is an optional field which ensures no other protocols (like Port Aggregation Protocol, PAgP) get negotiated. LACP active mode means that the local switch actively sends LACPDUs to try and establish the bond, while passive mode means a switch will respond to them. Two switches both running in passive mode cannot form LACP bonds, but two switches in active mode can. Both sides are configured as active on all ten ports. I also configure this as a trunk port to carry multiple VLANs if we decide to test that later, although LACP bonds can be access ports (or layer 3 routed ports). The configuration at the port level can be identical on both sides and for all ports in the bond. Since these ports were originally UNI ports, we also have to “no shutdown” them, as UNI ports are shutdown by default in this particular Metro IOS version.

```
! ME1 and ME2
interface range FastEthernet0/13 - 22
  port-type nni
  switchport mode trunk
  channel-protocol lacp
  channel-group 1 mode active
  spanning-tree portfast trunk
  no shutdown
```

With this very basic configuration, we can see that the bond comes up with no issues. Looking at ME1, we see that the first 8 ports are actively used in the bond, while the remaining 2 are in hot-standby mode. LACP supports up to 16 links in a bond, but only 8 can be used at once, with up to 8 standby links. PAgP and static Etherchannel do not support the hot-standby feature. The “SU” flags in the output indicate that the port-channel is in use and that it is switched (running at layer 2). ME2 has the exact same output and is not shown.

```
ME1#show etherchannel summary
Flags:  D - down                P - bundled in port-channel
        I - stand-alone s - suspended
        H - Hot-standby (LACP only)
        R - Layer3            S - Layer2
        U - in use           f - failed to allocate aggregator

        M - not in use, minimum links not met
        u - unsuitable for bundling
        w - waiting to be aggregated
```

d - default port

Number of channel-groups in use: 1
Number of aggregators: 1

Group	Port-channel	Protocol	Ports
1	Po1 (SU)	LACP	Fa0/13 (P) Fa0/14 (P) Fa0/15 (P) Fa0/16 (P) Fa0/17 (P) Fa0/18 (P) Fa0/19 (P) Fa0/20 (P) Fa0/21 (H) Fa0/22 (H)

Most of the time, the command above is the only command you really need to verify and troubleshoot LACP. We will examine advanced commands as well since they are not so well-known. First, we can look at the LACP neighbors. The device ID is the neighbor's MAC address which is also used for the STP bridge-ID MAC address component. We can prove this by checking the STP information on ME2. We can see all ten of the ports have the same neighbor ID since there is no multi-homed, multi-chassis LACP being tested here. All ports are using "slow" LACPDU's; this happens automatically once an Etherchannel is stable, which is a 30 second PDU timer. The "Age" column resets to 0 when an LACPDU is received and counts up to 30. During the initial setup, "fast" LACPDU's are sent which is once per second. We also see the port numbers are listed in hexadecimal which are just sequential numbers assigned to ports; this is similar to the STP port ID and is used as a tie-breaker for selecting active links (more on this later). The port state is a code, again similar to STP, which shows what the port is doing. We can see code 0x3D probably relates to forwarding while code 0x5 relates to hot-standby (or a general link-down state).

ME1#show lacp 1 neighbor

Flags: S - Device is requesting Slow LACPDU's
F - Device is requesting Fast LACPDU's
A - Device is in Active mode P - Device is in Passive mode

Channel group 1 neighbors

Partner's information:

```

Port	Flags	LACP port Priority	Dev ID	Age	Admin key	Oper Key	Port Number	Port
Fa0/13	SP	32768	04c5.a453.d800	16s	0x0	0x1	0x110	0x3C
Fa0/14	SP	32768	04c5.a453.d800	15s	0x0	0x1	0x111	0x3C
Fa0/15	SA	32768	04c5.a453.d800	19s	0x0	0x1	0x112	0x3D
Fa0/16	SA	32768	04c5.a453.d800	2s	0x0	0x1	0x113	0x3D

```

[snip]

```

LACP has the concept of a system-ID, which is loosely analogous to the STP bridge-ID. It is computed the same way; a 2 byte administratively-defined priority is prepended to the MAC address of the switch, and the lower value is considered the decision-maker in terms of which links are used for forwarding. Below, we can see the system-ID on both ME1 and ME2. Both have the default priority of 32768 and their switch global MAC addresses. ME1 has the lower MAC address and, as such, is the decision-maker on which links get aggregated.

```

ME1#show lacp sys-id
32768, 001d.4692.f700

ME2#show lacp sys-id
32768, 04c5.a453.d800

```

For variety, we will configure ME2 to be the LACP decision-maker by adjusting its system priority globally, then confirming the change. Changing the decision-maker, in this case from ME1 to ME2, will cause the bond to flap, so don't do it in production.

```

! ME2
lacp system-priority 16384

```

```
ME2#show lacp sys-id
16384, 04c5.a453.d800
```

We can change the port-priority to select which ports should be used for forwarding. Much like changing the STP port-priority on an upstream switch to influence root port selection on a downstream switch, this is configured on a per-interface basis to select usable ports. Our example has 10 ports, yet only 8 are used for forwarding. The 8 ports with the lowest port-ID (which is the concatenation of the port-priority and the port-number) are used for forwarding. That is why the first 8 ports are used, since their port-numbers as seen above are lower. We will reduce the port priorities of ports 21 and 22 on ME1 to observe the effect; we see that nothing changes.

```
! ME1
interface range FastEthernet0/21 - 22
 lacp port-priority 16384
```

Looking at the internal details of the bond, ME1 shows that the new port-priority was configured correctly yet the ports are stuck in hot-standby. This is because ME1 is no longer the decision-maker on which ports are used for forwarding in the bond as it has the higher LACP system-ID. This is equivalent to configuring port-priority on a downstream STP switch on the root port and expecting it to do something. Only ME2 can determine which ports can be used for forwarding, so ME1's port-priorities for this channel are meaningless.

```
ME1#show lacp internal | include 2[12]
Fa0/21    SA      hot-sby  16384      0x1      0x1      0x118      0x5
Fa0/22    SA      hot-sby  16384      0x1      0x1      0x119      0x5
```

We will use a similar configuration on ME2 to achieve the desired effect. This change also causes ports in the bond to flap, so don't do it in production. ME1 still shows its local port-priority of 16384, which is meaningless, but the ports are now active in the bundle since ME2 decided to do this. I show outputs from both ME1 and ME2 for clarity here; we can see that the port-priority column is a reflection of the local configuration only. Now, the next worse LACP port-IDs are placed into hot-standby mode, which are ports 19 and 20.

```
! ME2
interface range FastEthernet0/21 - 22
 lacp port-priority 8192
```

```
ME1#show lacp internal
[snip]
```

The “neighbor” command seen earlier reflects the remote peer configuration. On ME1, for example, we can see the remote port-priority on those newly-bundled ports. This is in contrast to the “internal” command which reflects the local configuration.

```
ME1#show lacp neighbor | include 2[12]
Fa0/21    SA      8192    04c5.a453.d800  17s    0x0    0x1    0x118    0x3D
Fa0/22    SA      8192    04c5.a453.d800   4s    0x0    0x1    0x119    0x3D
```

The detail version of the “internal” and “neighbor” commands will display a more verbose version of the tabular data for local and remote LACP fields, respectively. Snippets are shown below, but very little new information is provided, so we don’t analyze it. In this example, we look at ME2’s port 13 details (neighbor) and ME1’s port 13 details (internal), both from ME1’s perspective.

```
ME1#show lacp neighbor detail
[snip]
```

Port	Partner System ID	Partner Port Number	Age	Partner Flags

Collecting:	Distributing:	Defaulted:	Expired:
Yes	Yes	No	No

All of these details represent the same fields that are carried in LACPDUs during the bond negotiation. A short debugging effort on ME1 reveals some of these LACPDUs being sent. The “p-pri” and “s-pri” fields represent the port and system priorities, respectively, and are show in hexadecimal (0x8000 = 32768).

```
! ME1
ME1#debug lacp packet

```

Assuming I unplug one of the links actively in the bundle, the hot-standby links will take over for it. I unplug port 13, which means port 19 is the next most desirable port for forwarding. Notice that the line protocol is moved from down to up across interfaces in about one second. Port 20 still remains down, as LACP is holding it in this state given its high port-ID compared to the remaining ports.

```
! ME1
01:03:34: %LINEPROTO-5-UPDOWN: Line protocol on Interface FastEthernet0/13,
changed state to down
01:03:35: %LINK-3-UPDOWN: Interface FastEthernet0/13, changed state to down
```

```
01:03:35: %LINEPROTO-5-UPDOWN: Line protocol on Interface FastEthernet0/19,  
changed state to up
```

```
ME1#show interfaces fastEthernet 0/20 | include line_proto  
FastEthernet0/20 is up, line protocol is down (notconnect)
```

A quick check of the LACP internal information shows the first port as down, which interestingly has the same code of 0x5 as hot-standby. Port 19 is now in the bundle while port 20 remains in hot-standby.

```
ME1#show lacp internal  
[snip]
```

Port	Flags	State	LACP port Priority	Admin Key	Oper Key	Port Number	Port State

Fa0/22	SA	bndl	16384	0x1	0x1	0x119	0x3D

We plug port 13 in before continuing. Now that we have tested the high-availability and channel formation details, we will discuss the bandwidth benefits. These benefits are not specific to LACP and apply to all types of Ethernet link aggregation. Because this FastEthernet Etherchannel (FEC, not to be confused with MPLS forwarding equivalence class) consists of 8 active members, it has an aggregated bandwidth of 800 Mbps. This is important from an IGP perspective, because if we were running routing over this single logical link, we should prefer it more than a single 100 Mbps link, but less than a single 1 Gbps link. In the case of switching, STP takes this new bandwidth into account automatically; we know that classic STP uses a cost of 19 for 100 Mbps ports and 4 for 1 Gbps port. The cost of this 800 Mbps FEC is 5, which sounds right. This value of 5 is much better than 19 but just slightly worse than 4.

```
ME1#show interfaces port-channel 1 | include BW  
MTU 1998 bytes, BW 800000 Kbit/sec, DLY 100 usec,
```

```
ME1#show spanning-tree interface port-channel 1  
Vlan          Role Sts Cost          Prio.Nbr Type  
-----  
VLAN0001      Desg FWD 5           128.64  P2p
```

To achieve the load-sharing, Etherchannels can select from a variety of algorithms, and I show the context-sensitive help below with added comments. The term “IP” always includes IPv4, but may include IPv6 depending on the platform. Non-IP traffic (PPPoE, MPLS, CLNS, etc) is always load balanced based on MAC addresses since the IP-based load sharing doesn’t make sense.

```
ME1(config)#port-channel load-balance
dst-ip      Dst IP Addr ! Hashed based on destination IP address only
dst-mac     Dst Mac Addr ! Hashed based on destination MAC address only
src-dst-ip  Src XOR Dst IP Addr ! Hased based on source/dest IP address
src-dst-mac Src XOR Dst Mac Addr ! Hased based on source/dest MAC address
src-ip      Src IP Addr ! Hashed based on source IP address only
src-mac     Src Mac Addr ! Hashed based on source MAC address only
```

The load-balancing method is configured globally and the default on this platform is “src-mac”. We can verify this with a show command, and we see that both IP and non-IP traffic uses this method.

```
ME1#show etherchannel load-balance
EtherChannel Load-Balancing Configuration:
src-mac
```

```
EtherChannel Load-Balancing Addresses Used Per-Protocol:
Non-IP: Source MAC address
IPv4: Source MAC address
```

We can quickly test to see if this works. Each switch has a management SVI in VLAN 1, and the IP addresses for ME1 and ME2 are 10.0.10.91 and 10.0.10.92, respectively. We can test, using an exec command, to see which link is used when ME1 sends traffic to ME2 from this SVI, and vice versa. First, we need to record the MAC addresses of the SVIs.

```
ME1#show interfaces vlan 1 | include bia
Hardware is EtherSVI, address is 001d.4692.f740 (bia 001d.4692.f740)

ME2#show interfaces vlan 1 | include bia
Hardware is EtherSVI, address is 04c5.a453.d840 (bia 04c5.a453.d840)
```

Next, we issue the “test” commands on ME1 and ME2 to determine which member links will be used for these flows. Notice that the ports between switches don’t have to be the same, since the load-balancing decisions only affect how traffic is transmitted. Traffic can be received on any bundled link, since each switch can have a different load-sharing policy for traffic transmission.

```
ME1#test etherchannel load-balance interface port-channel 1 mac
001d.4692.f740 04c5.a453.d840
Would select Fa0/21 of Po1

ME2#test etherchannel load-balance interface port-channel 1 mac
04c5.a453.d840 001d.4692.f740
Would select Fa0/14 of Po1
```

Since the current load-sharing mechanism only cares about the source MAC, the destination MAC can change but the outgoing interface remains the same. We do a few bogus tests on ME1 to prove this.

```
ME1#test etherchannel load-balance interface port-channel 1 mac
001d.4692.f740 04c5.a453.2bad
Would select Fa0/21 of Po1
```

```
ME1#test etherchannel load-balance interface port-channel 1 mac
001d.4692.f740 04c5.a453.deed
Would select Fa0/21 of Po1
```

```
ME1#test etherchannel load-balance interface port-channel 1 mac
001d.4692.f740 04c5.a453.beef
Would select Fa0/21 of Po1
```

As a data-plane test, I will send many packets from ME2 to ME1, then check the counters while the flow is happening. We check port 14 on ME2 and port 21 on ME1 to see the packets increasing quickly.

```
ME2#ping 10.0.10.91 size 1500 repeat 1000000
```

```
ME1#show interfaces fastEthernet 0/21 | include packets_output
7055 packets output, 10339446 bytes, 0 underruns
```

```
ME2#show interfaces fastEthernet 0/14 | include packets_output
7127 packets output, 10368100 bytes, 0 underruns
```

For further proof, we can look at all the output packets on ME1 within the bond. It is obvious that one port has the most packets by far. Other ports are accounting for LACPDUs being transferred back and forth, along with any other flows that may be going between a different set of MAC addresses.

```
ME1#show interfaces | include packets_output
[snip]
2762 packets output, 237064 bytes, 0 underruns
341 packets output, 75578 bytes, 0 underruns
2932 packets output, 235918 bytes, 0 underruns
300 packets output, 64138 bytes, 0 underruns
306 packets output, 64906 bytes, 0 underruns
299 packets output, 63744 bytes, 0 underruns
290 packets output, 57346 bytes, 0 underruns
271 packets output, 50786 bytes, 0 underruns
7060 packets output, 10340618 bytes, 0 underruns
245 packets output, 40138 bytes, 0 underruns
```

We will test 2 other load sharing methods. ME1 will use the combination of source/destination IP while ME2 uses the combination of source/destination MAC. Notice that ME1 uses source/destination MAC load-sharing automatically for non-IP traffic, while ME2 uses this technique for both.

! ME1

```
port-channel load-balance src-dst-ip
```

```
! ME2
```

```
port-channel load-balance src-dst-mac
```

```
ME1#show etherchannel load-balance
```

```
EtherChannel Load-Balancing Configuration:  
    src-dst-ip
```

```
EtherChannel Load-Balancing Addresses Used Per-Protocol:
```

```
Non-IP: Source XOR Destination MAC address
```

```
    IPv4: Source XOR Destination IP address
```

```
ME2#show etherchannel load-balance
```

```
EtherChannel Load-Balancing Configuration:  
    src-dst-mac
```

```
EtherChannel Load-Balancing Addresses Used Per-Protocol:
```

```
Non-IP: Source XOR Destination MAC address
```

```
    IPv4: Source XOR Destination MAC address
```

With these new methods, we may get different results for our load sharing on both switches. ME1 coincidentally selects port 21 again while ME2 selects port 13. Notice that ME1 used IP addresses for input while ME2 used MAC addresses.

```
ME1#test etherchannel load-balance interface port-channel 1 ip 10.0.10.91  
10.0.10.92
```

```
Would select Fa0/21 of Po1
```

```
ME2#test etherchannel load-balance interface port-channel 1 mac  
04c5.a453.d840 001d.4692.f740
```

```
Would select Fa0/13 of Po1
```

We will clear counters on both switches and perform a short ping test of 100 packets. We can see that both switches have just over 100 packets (add in a few recent LACPDUs) on their selected outgoing interfaces.

```
ME2#ping 10.0.10.91 size 1500 repeat 100
```

```
ME1#show interfaces fastEthernet 0/21 | include packets_output  
    103 packets output, 152450 bytes, 0 underruns
```

```
ME2#show interfaces fastEthernet 0/13 | include packets_output  
    102 packets output, 152056 bytes, 0 underruns
```

As a note, when using the “test” command with an IP-based load-sharing scheme, the parser warns you that the result is not accurate for IP traffic. For example, if we used the MAC addresses as input on ME1,

we get a different output interface (port 13), which may not be true for IP traffic. Since ME1 does use this mechanism for non-IP traffic, this command is still valuable, but you must be diligent to provide the proper inputs depending on the traffic type. MPLS traffic exiting ME1 towards ME2 would actually use port 13, as an example.

```
ME1#test etherchannel load-balance interface port-channel 1 mac
001d.4692.f740 04c5.a453.d840
Configured load-balance is "src-dst-ip", results may not be accurate for IP
traffic
Would select Fa0/13 of Po1
```

Additional Reading – Reference configurations "lACP"

39.2 Uni-Directional Link Detection (UDLD)

UDLD is a feature that is designed to detect unidirectional links. It is generally used on fiber links where there are explicit and separate transit (TX) and receive (RX) fiber lines. Each set of TX/RX lines is called a “pair” and ideally, both TX and RX directions are functional. When one of the lines fails, the overall link does not perform as expected, and UDLD helps mitigate this. The network diagram is very simple and consists of two hardware Cisco ME-3400-24TS-A switches connected with a single fiber pair. The SFPs used are 100BaseFX, which is 100 Mbps.

First, we will configure the interfaces to support a basic fiber connection between the two. I hardcode the duplex to full since sometimes, in my experience, the FX SFPs will negotiate half-duplex. We cannot set the speed on these interfaces as this is controlled by the SFP hardware. UDLD is not yet enabled, but CDP is by default, and we will use that for verification assistance.

```
! ME1 and ME2
interface GigabitEthernet0/1
  description UDLD TEST
  port-type nni
  duplex full
```

We verify the basic link characteristics first. We see a 100Base-FX SFP with a speed of 100 Mbps, along with full-duplex operation. The interface hardware components appear to be working properly.

```
ME1#show interfaces gigabitEthernet 0/1 | include media_type|line_proto
GigabitEthernet0/1 is up, line protocol is up (connected)
Full-duplex, 100Mb/s, link type is auto, media type is 100BaseFX SFP
```

```
ME2#show interfaces gigabitEthernet 0/1 | include media_type|line_proto
GigabitEthernet0/1 is up, line protocol is up (connected)
Full-duplex, 100Mb/s, link type is auto, media type is 100BaseFX SFP
```

We can also see that CDP sees neighbors in both directions, which is a quick indication that the fiber pair is working. We are also able to ping between management SVIs, which is another verification method.

```
ME1#show cdp neighbors gigabitEthernet 0/1
Capability Codes: R - Router, T - Trans Bridge, B - Source Route Bridge
                  S - Switch, H - Host, I - IGMP, r - Repeater, P - Phone,
                  D - Remote, C - CVTA, M - Two-port Mac Relay
```

Device ID	Local Intrfce	Holdtme	Capability	Platform	Port ID
ME2	Gig 0/1	145	S I	ME-3400-2	Gig 0/1

```
ME2#show cdp neighbors gigabitEthernet 0/1
```

```
[snip]
```

Device ID	Local Intrfce	Holdtme	Capability	Platform	Port ID
ME1	Gig 0/1	136	S I	ME-3400-2	Gig 0/1

```
ME1#ping 10.0.10.92
```

```
Type escape sequence to abort.
```

```
Sending 5, 100-byte ICMP Echos to 10.0.10.92, timeout is 2 seconds:
```

```
!!!!
```

```
Success rate is 100 percent (5/5), round-trip min/avg/max = 1/4/9 ms
```

Now that we are certain the link is functional, we will enable UDLD. There are two modes of operation: normal and aggressive. In normal mode, when a unidirectional link is detected, UDLD does not take action. The port forwarding states will behave according to the STP topology. When a port is determined to be bi-directional (functional), once the UDLD message hold-down time expires without having seen UDLD messages from the remote end, the port is considered to be unidirectional. UDLD can be enabled globally or per-interface. When enabled globally, it only applies to fiber ports, but you can enable it on copper ports at the interface level. ME1 uses the global command and ME2 uses the port command; both are using UDLD normal mode. We can also disable UDLD on specific ports when it is enabled globally; on ME1, I demonstrate this by disabling UDLD on Gig0/2, a dummy port. In both cases, UDLD normal mode is enabled on Gig0/1 only on both switches.

```
! ME1
```

```
udld enable
```

```
interface GigabitEthernet0/2
```

```
udld port disable
```

```
! ME2
```

```
interface GigabitEthernet0/1
```

```
udld port
```

We can see the state of UDLD by checking the neighbors. The device name shown in the neighbor table is the remote device's serial number, which we prove by checking ME2.

```
ME1#show udld neighbors
```

Port	Device Name	Device ID	Port ID	Neighbor State
----	-----	-----	-----	-----
Gi0/1	FOC1510V51X	1	Gi0/1	Bidirectional

```
ME2#show version | include System_serial
```

```
System serial number      : FOC1510V51X
```

Often times, looking at the neighbor summary is sufficient for UDLD verification, but specifying an interface prints more detail. Specifically, we can see the message interval and timeout which are discussed later.

```
ME1#show udld gigabitEthernet 0/1
```

```

We can test UDLD by simply unplugging one of the lines on one of the pairs. Since the link is currently in the bidirectional state, this will change shortly, which should trigger UDLD. Unplugging the RX line on ME2 means that the ME2 interface goes down but ME1 stays up. There is nothing of interest to test on ME2 since the interface is down, but on ME1, we can see the UDLD and CDP neighbors are gone. However, the interface stays up, and is forwarding per STP. UDLD in normal mode isn't terribly useful and it doesn't generate a syslog message, either.

```
ME1#show udld neighbors
```

Port	Device Name	Device ID	Port ID	Neighbor State
----	-----	-----	-----	-----

[no output]

```
ME1#show cdp neighbors gigabitEthernet 0/1

Next, we will restore fiber connectivity and enable UDLD aggressive mode. This is also enabled globally or per-port, as we see on ME1 and ME2. UDLD remains disabled on ME1 Gig0/2 explicitly, so only Gig0/1 on both switches is UDLD-enabled. I also enable err-disable recovery on both switches so that after a UDLD failure is fixed, the port can be restored automatically.

```
! ME1
```

```
errdisable recovery cause udld
errdisable recovery interval 30
udld port aggressive
```

```
! ME2
```

```
errdisable recovery cause udld
errdisable recovery interval 30
```

```
interface GigabitEthernet0/1
  udld port aggressive
```

ME1 sees ME2 as a bidirectional neighbor again, except this time in aggressive mode. Aggressive mode will err-disable unidirectional links so that alternative paths can be used by STP and other protocols. This

only occurs after aggressive mode tries to recover the link by sending more frequent UDLD messages across; err-disable is the result of the recovery failure.

```
ME1#show udld neighbors
```

Port	Device Name	Device ID	Port ID	Neighbor State
Gi0/1	FOC1510V51X	1	Gi0/1	Bidirectional

```
ME1#show udld gigabitEthernet 0/1
```

```

```

```
Message interval: 15
```

```
Time out interval: 5
```

```
[snip]
```

Now, we unplug ME2 RX connection the break bidirectional connectivity, ME1's interface stays up until UDLD detects the broken connectivity. UDLD aggressive-mode prints syslog messages to notify us about this failure, then err-disables the port.

```
! ME1
```

```
02:49:49: %UDLD-4-UDLD_PORT_DISABLED: UDLD disabled interface Gi0/1,
```

```
aggressive mode failure detected
```

```
02:49:49: %PM-4-ERR_DISABLE: udld error detected on Gi0/1, putting Gi0/1 in  
err-disable state

state to down
```

```
02:49:50: %LINEPROTO-5-UPDOWN: Line protocol on Interface GigabitEthernet0/1,  
changed state to down
```

The port is now unusable; since there are no alternative paths, there are no interfaces in the "up" state on either switch, so connectivity is totally broken. If there were alternative paths, those would be used instead.

```
ME1#show interfaces gigabitEthernet 0/1 status
```

Port	Name	Status	Vlan	Duplex	Speed	Type
Gi0/1	UDLD TEST	err-disabled	1	full	100	100BaseFX SFP

```
ME1#show spanning-tree vlan 1
```

```
Spanning tree instance(s) for vlan 1 does not exist.
```

The err-disable recovery timer tries to recover the port every 30 seconds, so plugging the cable back in restores the port, and thus the UDLD error clears. We can see that in 6 seconds, the err-disable process

will attempt to recover this port, and the log messages from a successful recovery are shown below. Without the auto-recovery configured, manual “shutdown” and “no shutdown” commands are required. Alternatively, the “udld reset” command can be used.

```
ME1#show errdisable recovery | begin reason
Interface      Errdisable reason      Time left(sec)
-----
Gi0/1          udld                    6

%LINEPROTO-5-UPDOWN: Line protocol on Interface GigabitEthernet0/1, changed
state to up
```

We will break the link again to capture more debugging information. We can watch this UDLD behavior in action by looking at UDLD events on ME1 (or whichever switch still has its RX line connected). Before the failure, we see UDLD messages being exchanged every 15 seconds as expected.

```
ME1#debug udld events
UDLD events debugging is on

! ME1
02:58:36: New_entry = 55128D8 (Gi0/1)

02:58:51: Found my own ID pair in 2way conn list (Gi0/1)
```

Once we unplug the cable, the output changes. ME1 shows no output for about 45 seconds (3 times the hello interval) then declares that all neighbors on Gig0/1 have aged out. Then, UDLD aggressive mode sends 8 hellos 1 second apart to try and recover the link. After that, the link is considered down and is err-disabled.

```

! ME1
03:02:20: allNeighborsAgedOutEvent during link up. (Gi0/1)

```

We can plug the line back in and perform a manual CLI reset to fix the network so we can test it once more with the UDLD packet debugs. We would also wait for err-disable recovery, but the manual CLI reset is faster and more appropriate for testing.

```

ME1#udld reset
1 ports shutdown by UDLD were reset.

ME1#show interfaces gigabitEthernet 0/1 status
Port      Name      Status      Vlan    Duplex  Speed Type
Gi0/1     UDLD TEST connected    1       full    100 100BaseFX SFP

```

With the network stable again, I break the network once more by unplugging the RX line from ME2. Packet debugging has been enabled on ME1 so we can see the UDLD activity, as well as aggressive mode trying to recover the link. The first two probes are ordinary messages and are sent 15 seconds apart. Once UDLD sees the issues, it issues 8 “resynch” messages in quick succession, once per second, until it flushes the UDLD state from the database. I personally think aggressive mode is a much better option than normal mode. I would not consider this “high” availability since it takes almost a minute to detect and bypass the failure.

```

ME1#debug udld packets
UDLD packets debugging is on

! ME1
03:09:48: UDLD send probe message, flags = rec_timeout (Gi0/1)

03:10:25: UDLD send flush message, flags = 0 (Gi0/1)
03:10:25: F (Gi0/1)
03:10:25: %UDLD-4-UDLD_PORT_DISABLED: UDLD disabled interface Gi0/1,
aggressive mode failure detected

```

The only knob that UDLD has available is how often UDLD messages are sent in steady-state operation. This can speed up UDLD “convergence”. The default is 15 seconds, but we can adjust it to any number between 1 and 90. I adjust it to 10 on ME1 only, since the timers don’t have to match. Once we set this, the details reveal it. ME1 uses a timer of 10, while it learns that ME2 uses the default timer of 15.

```

! ME1
udld message time 10

ME1#show udld gigabitEthernet 0/1 | include Message|Device
Message interval: 10
  Device ID: 1
  Device name: FOC1510V51X
  Message interval: 15
  CDP Device name: ME2

```

UDLD packet debugging reveals this new timer in use. I omit the received probe information since it is verbose and not valuable for this verification. We can see ME1 sending probes 10 seconds apart now.

```

ME1#debug udld packets
UDLD packets debugging is on

03:15:29: UDLD send probe message, flags = rec_timeout (Gi0/1)
03:15:29: P (Gi0/1)
03:15:39: UDLD send probe message, flags = rec_timeout (Gi0/1)
03:15:39: P (Gi0/1)

```

40. Describe, implement, and troubleshoot Layer 3 failure detection

40.1 Individual Protocol Hello packets

Most protocols have their own neighbor discovery mechanism, which is typically a hello packet of sorts. This is true for EIGRP, OSPF, IS-IS, RSVP, FHRPs, BGP, LDP, PIM, and others. There are typically two timers associated with each: an interval that determines how frequently to send hellos, and a hold/dead timer that says how long one can go without receiving one before declaring the neighbor dead. The timer behavior varies significantly between protocols and is discussed in this section. The network diagram includes XE and XR routers to see the configuration/verification on both platforms.

First, we will examine OSPF timers briefly. The hello and dead timers must match on all peers sharing an interface/network. This can be changed per-link. The hello/dead timers are easily understood and there are no magic tricks with OSPF. If the dead-interval is not specified, it is automatically assumed to be four times the hello interval. We will adjust the hello/dead timers to 2/6 seconds on the OSPF LAN.

```
! CSR8, CSR9, CSR10
interface GigabitEthernet2.518
 ip ospf dead-interval 6
 ip ospf hello-interval 2

! XRV1
router ospf 181
 area 0
 interface GigabitEthernet0/0/0/0.518
  dead-interval 6
  hello-interval 2
```

A quick debug on XRv1 and CSR8 shows hellos being send and received as expected. XR shows more detailed output to include the DR/BDR information, timers, and other pieces of information.

```
RP/0/0/CPU0:XRv1#debug ospf 181 hello gig0/0/0/0.518

OSPF-181 HELLO Gi2.518: Rcv hello from 181.0.0.9 area 0 181.18.90.9
```

We will configure CSR9 to have a different set of timers so that the neighborhood fails. Both XE and XR show these failures in the debug messages. Both XE and XR output uses “R” and “C” for Remote and Configured, respectively. The remote value is what the peer is using, while configured is the local value. We can see that CSR9 is using a dead time of 13 and a hello time of 6, while CSR8 expects a dead time of 6 and a hello time of 2. The subnet mask also much match on broadcast links, and in this case, it does.

```
! CSR9
interface GigabitEthernet2.518
 ip ospf dead-interval 6
 ip ospf hello-interval 13

! CSR8
OSPF-181 HELLO Gi2.518: Rcv hello from 181.0.0.9 area 0 181.18.90.9

hello from 181.0.0.9 area 0 failed validation
```

Before continuing, we will set CSR9 back to the proper values (not shown). We will quickly verify the timers on CSR9 as well as the neighbors. CSR9 is a DR/BDR candidate and should have full adjacencies with all nodes on the segment.

```
R9#show ip ospf interface gig2.518 | include Timer
Timer intervals configured, Hello 2, Dead 6, Wait 6, Retransmit 5
```

```
R9#show ip ospf neighbor gig2.518
```

Neighbor ID	Pri	State	Dead Time	Address	Interface
181.0.0.8	0	FULL/DROTHER	00:00:05	181.18.90.8	Gig2.518
181.0.0.10	3	FULL/BDR	00:00:05	181.18.90.10	Gig2.518
181.18.90.11	0	FULL/DROTHER	00:00:04	181.18.90.11	Gig2.518

For the fastest possible OSPF detection, we can set the dead timer to “minimal”, which is 1 second. We then specify how many hellos packets should be sent within that 1 second interval. A smaller number means less frequent hello packets. Below, we set the dead interval to 1 second with the hello interval to 1/3 of a second, or 333ms. OSPF can send hellos as fast as 50ms apart using a hello-multiplier of 20 (1/20th of a second). To ensure I don’t violate the CSR1000v 100 kbps bandwidth constraint, I only configure this on the link between CSR5 and CSR10. We also verify the timers are correct and that a neighbor has formed. We can verify this on one side, since a timer mismatch implies no neighbor. Notice the very short dead timer.

```
! CSR5 and CSR10
interface GigabitEthernet2.550
ip ospf dead-interval minimal hello-multiplier 3
```

```
R5#show ip ospf interface gig2.550 | include Timer
Timer intervals configured, Hello 333 msec, Dead 1, Wait 1, Retransmit 5
```

```
R5#show ip ospf neighbor gig2.550
```

Neighbor ID	Pri	State	Dead Time	Address	Interface
181.0.0.10	0	FULL/ -	990 msec	181.5.10.10	GigabitEthernet2.550

OSPFv3 is similar. We will use a hello timer of 2 and a dead timer of 8 for routers on the LAN. We quickly verify the timers as well.

```
! CSR8, CSR9, and CSR10
interface GigabitEthernet2.518
  ospfv3 181 hello-interval 2
  ospfv3 181 dead-interval 8
```

```
! XRv1
router ospfv3 181
  interface GigabitEthernet0/0/0/0.518
    dead-interval 8
    hello-interval 2
```

```
R9#show ospfv3 interface gig2.518 | include Timer
Timer intervals configured, Hello 2, Dead 8, Wait 8, Retransmit 5
```

```
RP/0/0/CPU0:XRv1#show ospfv3 interface gig0/0/0/0.518 | include Timer
Timer intervals configured, Hello 2, Dead 8, Wait 8, Retransmit 5
```

Because OSPFv2 fast hellos existed before BFD (discussed later) and OSPFv3 was created later, there was no good reason to support OSPFv3 fast hellos. Thus, like EIGRP, the slowest hello-interval is 1 second. By only specifying this, the dead-timer is automatically 4 times this value, which is 4 seconds.

```
! CSR5 and CSR10
interface GigabitEthernet2.550
  ospfv3 181 hello-interval 1
```

```
R10#show ospfv3 interface gig2.550 | include Timer
Timer intervals configured, Hello 1, Dead 4, Wait 4, Retransmit 5
```

IS-IS has a slightly different behavior with respect to matching timers. Timers do not need to match on both sides, and the IS-IS hellos carry a “hold-time” value. This value tells a peer “if you don’t receive a hello from me within this time period, consider me dead”. In this way, a different set of timers can be established per node. By default, the hold-time is 3 times the hello time, which is considered the hello-multiplier. Like many IS-IS commands, we can optionally specify the level to which these hellos apply. Since XRv1 is the DIS, the logic changes to act like the “minimal” configuration. That is to say, the hello interval is divided by the multiplier, but only on the DIS. If we want a 2 second hello interval from the DIS, we can use 6/3. Below, we configure different hello/hold timers on all 4 routers.

```
! XRv1
router isis 181
  interface GigabitEthernet0/0/0/0.513
    hello-interval 6
    hello-multiplier 3
```

```
! XRv3
router isis 181
```

```

interface GigabitEthernet0/0/0/0.513
  hello-interval 2 level 2

! CSR4
interface GigabitEthernet2.513
  isis hello-interval minimal
  isis hello-multiplier 3

! CSR10
interface GigabitEthernet2.513
  isis hello-interval 6 level-2

```

Based on this configuration, XRv1 uses 2/6, XRv3 uses 2/3 (3 is the default hello-multiplier), CSR4 uses 333ms/1 (similar to OSPF fast hellos), and CSR10 uses 6/18. The verification for this is very loose; we cannot clearly see the timer configuration for either XE or XR. We can only look at the interface details to see when the “next” hello packet will be sent.

```

R4#show clns interface gig2.513 | include Hello
Next IS-IS LAN Level-2 Hello in 196 milliseconds

```

```

R10#show clns interface gig2.513 | include Hello
Next IS-IS LAN Level-2 Hello in 3 seconds

```

```

RP/0/0/CPU0:XRv3#show isis interface gig0/0/0/0.513 | include IIH
Next LAN IIH in:      1 s

```

```

RP/0/0/CPU0:XRv1#show isis interface gig0/0/0/0.513 | include IIH
Next LAN IIH in:      461 ms

```

Likewise, when looking at a neighbor, we can see the hold-time as it counts down, but not the neighbors configured value. From the DIS’ perspective, CSR4’s hold-time is sub-second so the value shows as 0. CSR10 has a hold time of 18 (6 * 3) so a number like 16 makes sense. XRv3’s hold time is 6 seconds (2 * 3) so a number like 5 makes sense.

```

RP/0/0/CPU0:XRv1#show isis neighbors
IS-IS 181 neighbors:

```

System Id	Interface	SNPA	State	Holdtime	Type	IETF-NSF
R4	Gi0/0/0/0.513	0050.56a9.2c57	Up	0	L2	Capable
R10	Gi0/0/0/0.513	0050.56a9.f961	Up	16	L2	Capable
XRv3	Gi0/0/0/0.513	0050.56a9.ea54	Up	5	L2	Capable

To prove the awkwardness of the DIS timers, we can enable IS-IS hello debugging on XRv1 and CSR10. XRv1 will receive many hellos from CSR4 because it has a sub second hello interval (omitted). We can see the hello packets being originated from XRv1 using the DIS’ hostname-based NET (XRv1.01), and being sent every ~2 seconds despite configuring a 6 second hello interval (6 / 3).

```

```

CSR10 receives hellos from all other neighbors (shown by MAC address) which all show the DIS' NET minus the area (0000.0000.0011.01). Hellos can be jittered up to 25% so the interval is not exactly 2 seconds. Also, we see that CSR10 sends a single hello for every ~3 received from the DIS as its interval is 3 times slower.

EIGRP behaves similarly to IS-IS with respect to its per-neighbor treatment of hello/hold timers. The difference is that there isn't a pseudonode concept since EIGRP is not link-state, so the additional complexity observed in IS-IS doesn't apply. EIGRP also does not have a sub-second hello option, so the fastest possible failure detection is 1 second; hello timer is 1 second with a 1 second hold-time. This is probably highly unstable and a hold-time of at least 2 seconds would be preferred in this case. There is no difference between IPv4 and IPv6, so only IPv4 is examined here. XRv3 and CSR2 have timer adjustments shown below, while CSR4 uses the default timers of 5/15 (no configuration changes).

```

! CSR2
router eigrp L3
  address-family ipv4 unicast autonomous-system 181
    af-interface default
      hello-interval 4
      hold-time 16

! XRv3
router eigrp L3
  vrf L3
    address-family ipv4
      interface GigabitEthernet0/0/0/0.523
        hello-interval 3
        hold-time 9

```

We can quickly verify the configuration was successful by checking the interface details. Notice that all of the timers are different.

```

R4#show eigrp address-family ipv4 vrf L3 interfaces detail | include Hello-
Hello-interval is 5, Hold-time is 15

```

```

R2#show eigrp address-family ipv4 interfaces detail | include Hello-
Hello-interval is 4, Hold-time is 16

```

```

RP/0/0/CPU0:XRv3#show eigrp vrf L3 ipv4 interfaces detail | include Hello
Hello interval is 3 sec, hold time is 9 sec

```

Checking the EIGRP neighbors on CSR2, we can see the per-neighbor hold times, just like IS-IS. XRv3 has a hold time of 9 seconds, so a value of 8 makes sense. CSR4 has a hold time of 16 seconds, so a value of 12 makes sense. Similarly for XRv3, CSR4 and CSR2 both have reasonable hold times (that is, values less than or equal to their configured hold times), which shows a correct configuration.

RIP timers aren't really used for failure detection since RIP packets actually carry routes; it doesn't have a dedicated neighbor discovery/maintenance mechanism. We can change the frequency at which the routing advertisements are sent, invalidated, and flushed. We use RIP and RIPvng as the PE-CE routing protocol between CSR5 and CSR6 for a quick demonstration. The only caveat is that the remote hello timer must be less than the local invalid timer. If it isn't, then the routing advertisements will come in too slowly, and the receiving router will have periods of downtime since the routers are flushed too quickly. Below is an example of this phenomenon. CSR5 uses the default timers (30/180/180/240) while CSR6 uses new, aggressive timers. CSR6 sends updates every 5 seconds and flushes received updates after 15 seconds. CSR5 is sending updates every 30 seconds yet CSR6 can only retain the for 15 seconds. For the remaining ~15 seconds, CSR6 will have no routes from CSR5. CSR6's advertisements are shown in yellow, and the received routes and subsequent downtime is shown in green.

```

To fix it, we mirror the timers on CSR5 under the VRF. Additionally, we configure “fast” timers on both nodes for RIPng as well. Also note that RIPng is not VRF away by default and requires a global command to enable that feature set (this would have been done during the initial L3VPN setup, but I draw attention to it here).

```

! CSR5
ipv6 rip vrf-mode enable

router rip
 address-family ipv4 vrf L3
   timers basic 5 15 15 20

ipv6 router rip L3
 address-family ipv6 vrf L3
   timers 5 15 15 20

! CSR6
ipv6 router rip CUST
 timers 5 15 15 20

```

We can verify updates are being passed back and forth successfully. We can see packets being sent and received 5 seconds apart, which is correct. Updates in green are being sent from CSR6 and updates in yellow are received by CSR6 from CSR5.

```

HSRP timers must match for the process to converge, but they can be configured differently. Whichever device is the active router for a given group will propagate its timers to the standby nodes. In this way, the configuration need not match, since the HSRP process ensures the timers are carried in the hello messages. This is similar to STP where the timers of the root bridge are carried in BPDUs for all non-root switches to honor, but individually switches can have entirely different timer settings. The default HSRP timers are 3/10 for hello/hold, so we will modify it to 4/12 on XRv3, while leaving the CSR4 timers unchanged.

```

! XRv3
router hsrp

```

```

interface GigabitEthernet0/0/0/0.523
  address-family ipv4
    hsrp 234 version 2
    timers 4 12

```

We can clearly see that XRv3 is the active router based on its higher priority (configuration not shown). CSR4 is the standby router but has inherited the new timers. XRv3 also shows us the configured timers as well, so comparing the configured and real-time timers is easier.

```

RP/0/0/CPU0:XRv3#show hsrp gig0/0/0/0.523 234
IPv4 Groups:

```

```

          P indicates configured to preempt.
          |

```

```

RP/0/0/CPU0:XRv3#show hsrp gig0/0/0/0.523 234 detail | include [Hh]ello
Hellotime 4000 msec holdtime 12000 msec
Configured hellotime 4000 msec holdtime 12000 msec

```

Since CSR4 is the active router for IPv6 hosts, we will change its timers using the smallest possible values, which is 15 ms and 50 ms. XRv3 accepts this value as it is learned via HSRP exchanges via the active router. Since HSRP runs different instances for IPv4 and IPv6, the two topologies can achieve rudimentary load-sharing (and entirely different configurations) in this way.

```

! CSR4
interface GigabitEthernet2.524
  standby 236 timers msec 15 msec 50

```

```

R4#show standby gig2.524 236 | include State|Hello
State is Active
Hello time 15 msec, hold time 50 msec

```

```

RP/0/0/CPU0:XRv3#show hsrp gig0/0/0/0.523 236 detail | include Hello
Hellotime 15 msec holdtime 50 msec

```

For debugging purposes, HSRP 236 is temporarily disabled to avoid flooding the log buffer/console. We will look at the IPv4 exchanges. Even with detailed debugging, there isn't much to see. The packets contain their timers, priorities, interface MAC addresses, and virtual IP addresses. The in/out hello packets show the source IP of the packet received as the destination is multicast (224.0.0.102 for HSRPv2). We can see that packets are sent ~4 seconds apart in either direction.

```

R4#debug standby packets hello detail
23:05:30.380: HSRP: Gi2.524 Grp 234 Hello out 10.23.4.4 Standby pri 100 vIP
10.23.4.254

23:05:35.970:      hel 4000 hol 12000 id 0050.56a9.ea54

```

XRv3's debugging is very similar to CSR4's, showing the hello packets and their contents. One interesting difference is that XR doesn't appear to show outgoing HSRP packets, only incoming ones.

```

RP/0/0/CPU0:XRv3#debug hsrp packets hello detail
23:10:06.699 : hsrp[1095]: SB234: Gi0/0/0/0.523 Hello in 10.23.4.4

```

BGP timers can be configured differently on both sides, but the hold-time must match (after negotiation) for the session to form. BGP sessions use hello/hold timers of 60/180 by default on Cisco routers. Before doing anything, we will verify the default timers on CSR8. I show internal and external VPNv4 sessions and a single external VPNv6 session to prove it.

```

R8#show bgp vpnv4 unicast all neighbors | include ^BGP|hold_time
BGP neighbor is 7.7.7.7, vrf L3, remote AS 7, external link
  Last read 00:00:17, last write 00:00:32, hold time is 180, keepalive
interval is 60 seconds
BGP neighbor is 181.0.0.4, remote AS 181, internal link
  Last read 00:00:28, last write 00:00:37, hold time is 180, keepalive
interval is 60 seconds
BGP neighbor is 181.0.0.5, remote AS 181, internal link
  Last read 00:00:16, last write 00:00:43, hold time is 180, keepalive
interval is 60 seconds
BGP neighbor is 181.0.0.13, remote AS 181, internal link
  Last read 00:00:10, last write 00:00:46, hold time is 180, keepalive
interval is 60 seconds

R8#show bgp vpnv6 unicast vrf L3 neighbors fd00:10:7:8::7 | include hold_time
  Last read 00:00:00, last write 00:00:22, hold time is 180, keepalive
interval is 60 seconds

```

The hold-time is negotiated as part of the BGP session establishment where the smaller (faster) values are preferred. We can set a lower interval on XRv3 to prove this. A side effect of this is that the router who acknowledged the adjustment (CSR8, in this case) adjusts its keepalive interval to 1/3 of the new, smaller hold-time. This means the hello-interval decreases proportionally to the hold-time. In this case, XR follows suit and also uses 58 seconds despite being configured for 60.

```
! XRv3
router bgp 181
 neighbor 181.0.0.8
  timers 60 175
```

```
R8#show bgp vpnv4 unicast all neighbors 181.0.0.13 | include hold_time
Last read 00:00:37, last write 00:00:37, hold time is 175, keepalive
interval is 58 seconds
```

```
RP/0/0/CPU0:XRv3#show bgp vpnv4 unicast neighbors 181.0.0.8 | include hold
time
Hold time is 175, keepalive interval is 58 seconds
Configured hold time: 175, keepalive: 60, min acceptable hold time: 3
```

A more extreme example would be setting much lower timers, such as 10/40, and observing the remote side. We configure 10/40 timers on CSR8 towards CSR5, who then calculates its new keepalive timer as 13 seconds. Like in XR, there is a difference between configured and actual hold times. When a local node makes explicit changes to a timer, the two sets of timers are shown together. Unlike XR, it seems that XE is less generous; it still uses its configured keepalive timer despite CSR5 adjusting its timer proportionally. Asymmetric timers are typically undesirable and add complexity while yielding little gain.

```
! CSR8
router bgp 181
 neighbor 181.0.0.5 timers 10 40
```

```
R5#show bgp vpnv4 unicast all neighbors 181.0.0.8 | include hold_time
Last read 00:00:00, last write 00:00:03, hold time is 40, keepalive
interval is 13 seconds
```

```
R8#show bgp vpnv4 unicast all neighbors 181.0.0.5 | include hold_time
Last read 00:00:06, last write 00:00:08, hold time is 40, keepalive
interval is 10 seconds
Configured hold time is 40, keepalive interval is 10 seconds
```

As a security mechanism to protect the router's control-plane from too many BGP keepalives, we can specify a minimum neighbor hold-time. This allows a BGP speaker to reject sessions that have overly aggressive hold-timers; this is ideal for PE routers. By default, this is set to 0, allowing any hold-down timers. We can verify this by checking CSR5, as an example.

```
R8#show bgp vpnv4 unicast all neighbors 181.0.0.5 | include Minimum
```

Minimum holdtime from neighbor is 0 seconds

We will configure CSR8, as a PE, to ensure CSR7 is using at least a 60 second hold-down timer. Because we have not changed CSR7 yet, and we know the default was 180, we can assume CSR7 will negotiate a hold-time of 60 when peering with CSR8. This is an acceptable hold-time. We verify these timers on CSR7 and CSR8; again we see that XE is stubborn and uses its locally configured values, despite the remote peer calculating its keepalive to be 1/3 of the negotiated hold-down timers.

```
! CSR8
router bgp 181
 address-family ipv6 vrf L3
  neighbor FD00:10:7:8::7 timers 15 60 60
```

```
R8#show bgp vpnv6 unicast vrf L3 neighbors FD00:10:7:8::7 | include
hold_?time
  Last read 00:00:15, last write 00:00:06, hold time is 60, keepalive
interval is 15 seconds
  Configured hold time is 60, keepalive interval is 15 seconds
  Minimum holdtime from neighbor is 60 seconds
```

```
R7#show bgp ipv6 unicast neighbors FD00:10:7:8::8 | include hold_?time
  Last read 00:00:00, last write 00:00:09, hold time is 60, keepalive
interval is 20 seconds
```

Assuming CSR7 wanted to use an aggressive hold-time, the PE would not allow it, and the session does not form. Both CSR7 and CSR8 generate BGP log messages to detail this error. CSR7 tries to use a hold-time of 59 seconds which is “too fast” for CSR8. The syslog messages make this error very apparent.

```
! CSR7
router bgp 181
  neighbor FD00:10:7:8::8 timers 15 59
```

```
! CSR8
%BGP-3-NOTIFICATION: sent to neighbor FD00:10:7:8::7 active 2/6 (unacceptable
hold time) 0 bytes
```

```
! CSR7
%BGP-3-NOTIFICATION: received from neighbor FD00:10:7:8::8 active 2/6
(unacceptable hold time) 0 bytes
```

This isn't very useful for the customer, since they legitimately may not know what the hold-time is supposed to be. The BGP debugs don't help, either, so the customer would need to contact the provider. Assume that the issue was fixed and that CSR7 is now using a hold-time of 60 seconds again. Debugging on CSR7 towards CSR8, we can see CSR8 sending keepalives to CSR7 every ~15 seconds (yellow). CSR7 is sending keepalives to CSR8 every ~20 seconds as well (green), and these values don't need to match.

```
R7#debug bgp ipv6 unicast keepalives
```

```
00:28:56.997: BGP: FD00:10:7:8::8 received KEEPALIVE, length (excl. header) 0
```

```

```

```
00:29:02.756: BGP: FD00:10:7:8::8 KEEPALIVE requested  
(bgp_keepalive_timer_expired)
```

```
00:29:02.756: BGP: ses global FD00:10:7:8::8 (0x7F401571BBC8:1) service  
keepalive IO request.
```

```
00:29:02.756: BGP: FD00:10:7:8::8 KEEPALIVE write request serviced in BGP_IO
```

```
00:29:10.310: BGP: FD00:10:7:8::8 received KEEPALIVE, length (excl. header) 0
```

```
00:29:20.164: BGP: ses global FD00:10:7:8::8 (0x7F401571BBC8:1) Keep alive timer fired.
```

```
00:29:20.164: BGP: FD00:10:7:8::8 KEEPALIVE requested  
(bgp_keepalive_timer_expired)
```

```
00:29:20.165: BGP: ses global FD00:10:7:8::8 (0x7F401571BBC8:1) service  
keepalive IO request.
```

```
00:29:20.165: BGP: FD00:10:7:8::8 KEEPALIVE write request serviced in BGP_IO
```

```
00:29:24.648: BGP: FD00:10:7:8::8 received KEEPALIVE, length (excl. header) 0
```

For completeness, we will do the same debugging on XRv3. Since XR is more generous than XE, it has reduced its keepalive timer to 58 seconds, along with CSR8, so we should be keepalives at approximately the same interval. Keepalives sent to CSR8 occur every ~58 seconds (yellow), and keepalives received from CSR8 also occur every ~58 seconds as expected (green). This simplifies debugging by ensuring that both the hello and hold timers are synchronized.

```
RP/0/0/CPU0:XRv3#debug bgp keepalive 181.0.0.8
```

```
00:36:25.824 : bgp[1052]: [default-ka]: Keepalive timer expired for 181.0.0.8
```

```
00:36:25.824 : bgp[1052]: [default-ka]: Keepalive timer started for  
181.0.0.8(loc 5)
```

```
00:36:25.824 : bgp[1052]: [default-ka]: KEEPALIVE sent to 181.0.0.8
```

```
00:36:35.864 : bgp[1052]: [default-iord]: KEEPALIVE received from 181.0.0.8
```

```
00:37:23.841 : bgp[1052]: [default-ka]: Keepalive timer expired for 181.0.0.8
```

```
00:37:23.841 : bgp[1052]: [default-ka]: Keepalive timer started for  
181.0.0.8(loc 5)
```

```
00:37:23.841 : bgp[1052]: [default-ka]: KEEPALIVE sent to 181.0.0.8
```

```
00:37:31.160 : bgp[1052]: [default-iord]: KEEPALIVE received from 181.0.0.8
```

PIM hellos are also very straightforward and the hold-time is non-configurable. It is automatically 3.5 times the hello timer received from each neighbor. As such, the timers can be completely different like EIGRP and IS-IS. The default hello timer is 30; we reduce it to 15 on CSR4 and 3 on XRv3 for IPv4/v6.

! CSR4

```

interface GigabitEthernet2.524
  ip pim query-interval 15
  ipv6 pim hello-interval 15

! Xrv3
router pim
vrf L3
  address-family ipv4
    hello-interval 3
  address-family ipv6
    hello-interval 3

```

We can quickly confirm the configuration was correct by checking the interface details on both routers for both address-families.

```

R4#show ip pim vrf L3 interface detail | include Hello
PIM Hello/Query interval: 15 seconds
PIM Hello packets in/out: 34334/36527

```

```

R4#show ipv6 pim vrf L3 interface gig2.524

Interface          PIM    Nbr    Hello    DR
                  Count  Intvl  Prior
GigabitEthernet0/0/0/0.523  on     2      3      1
  Primary Address : fe80::13
  DR : this system

```

We will debug the IPv4 PIM hellos to show the variance in timers. Yellow represents CSR4 sending PIM hellos every 15 seconds, while green represents receiving PIM hellos from XRv3 every 3 seconds. Of note, IPv6 PIM requires non-LL addressing, unlike many other IPv6 protocols, and the PIMv6 hello debug is very verbose.

```

R4#debug ip pim vrf L3 hello
23:31:48.447: PIM(1): Send periodic v2 Hello on GigabitEthernet2.524 with
GenID = 2707292449

```

```

23:31:48.536: PIM(1): Received v2 hello on GigabitEthernet2.524 from
10.23.4.13
23:31:48.536: PIM(1): Ignored unknown option 2 in PIM Hello packet
23:31:48.536: PIM(1): Neighbor (10.23.4.13) Hello GENID = 21332

23:31:51.635: PIM(1): Received v2 hello on GigabitEthernet2.524 from
10.23.4.13
23:31:51.635: PIM(1): Ignored unknown option 2 in PIM Hello packet
23:31:51.635: PIM(1): Neighbor (10.23.4.13) Hello GENID = 21332

23:31:54.735: PIM(1): Received v2 hello on GigabitEthernet2.524 from
10.23.4.13
23:31:54.735: PIM(1): Ignored unknown option 2 in PIM Hello packet
23:31:54.735: PIM(1): Neighbor (10.23.4.13) Hello GENID = 21332

23:31:57.840: PIM(1): Received v2 hello on GigabitEthernet2.524 from
10.23.4.13
23:31:57.840: PIM(1): Ignored unknown option 2 in PIM Hello packet
23:31:57.840: PIM(1): Neighbor (10.23.4.13) Hello GENID = 21332

23:32:00.945: PIM(1): Received v2 hello on GigabitEthernet2.524 from
10.23.4.13
23:32:00.945: PIM(1): Ignored unknown option 2 in PIM Hello packet
23:32:00.945: PIM(1): Neighbor (10.23.4.13) Hello GENID = 21332

23:32:03.197: PIM(1): Send periodic v2 Hello on GigabitEthernet2.524 with
GenID = 2707292449

```

The XR debugs are concise, so much so that receiving a PIM hello doesn't even show the originator's IP address. It only indicates that a packet has been "read". Considering that this "read" event occurs ~15 seconds apart and there is only one other PIM router on the segment, we can assume this is from CSR4(yellow). The XRV3 originated packets are ~3 seconds apart, as expected (green).

```

40.2 Bidirectional Forwarding Detection (BFD)

Bidirectional Forwarding Detection (BFD) is a lightweight keepalive protocol design to reduce dead peer detection time across layer 2 networks. It is used primarily on networks that do not rely on line-protocol for interface status (like Ethernet). BFD uses a pair of UDP ports for transport and allows other protocols to "register" to it. BFD relies on a single session between its neighbors so that protocol-specific hello messages don't need to be aggressively tuned for fast fall-over. Individual protocols can be configured to use BFD; by default, none of them do. Some of these client protocols include EIGRP, OSPFv2/3, IS-IS, BGP, RSVP-TE, PIM, and xconnect. BFD uses echo messages to test reachability between neighbors and control messages for signaling. BFD does not perform neighbor detection; it relies on the registered protocol to do that, then runs probes based on those discovered IPv4/v6 neighbor addresses. The network diagram is shown below; large LANs are used for certain protocols rather than P2P links to demonstrate BFD behavior. It is similar to the previous section without XRv in the core as XRv does not support BFD (XRv1 is swapped with CSR1 and XRv3 is replaced by CSR3).

The echo function is on by default if you just enable BFD at link level using "bfd interval". Echoes are supported in BFD version 1, where version 0 only supported control packets. We can tell if echo is enabled by checking the BFD neighbor details. The OSPF LAN is configured using this method; the difference between echo and control packets are discussed later. One interesting note about BFD with OSPF is that, on broadcast networks, BFD sessions only form to the DR/BDR. In this case, CSR1 and CSR8 are not eligible to participate in the DR election, and thus do not form BFD peers with one another. Only CSR9 and CSR10 can be the BD/BDR.

```
! CSR1, CSR8, CSR9, CSR10
interface GigabitEthernet2.518
  bfd interval 900 min_rx 900 multiplier 3
```

```
R1#show bfd neighbors client ospf
```

```
IPv4 Sessions
```

NeighAddr	LD/RD	RH/RS	State	Int
181.18.90.9	4103/4100	Up	Up	Gi2.518

181.18.90.10	4098/4101	Up	Up	Gi2.518

```
R10#show bfd neighbors client ospf
```

```
IPv4 Sessions
```

NeighAddr	LD/RD	RH/RS	State	Int
181.5.10.5	4102/4097	Up	Up	Gi2.550
181.18.90.1	4106/4104	Up	Up	Gi2.518
181.18.90.8	4103/4100	Up	Up	Gi2.518
181.18.90.9	4101/4098	Up	Up	Gi2.518

We can also check the OSPF process to ensure BFD is enabled. From CSR10, we can check an OSPF neighbor, interface, or process to see if BFD is enabled or not. BFD needs to be bound to OSPF (or any other protocol) on a per-interface basis. Using the command below under the OSPF process registers OSPF to BFD on all interfaces, which is typically desired.

```
! CSR1, CSR8, CSR9, CSR10
router ospf 181
  bfd all-interfaces
```

```
R10#show ip ospf neighbor 181.0.0.1 | include BFD
    In the area 0 via interface GigabitEthernet2.518, BFD enabled
```

```
R10#show ip ospf interface gig2.518 | include BFD
    Transmit Delay is 1 sec, State BDR, Priority 3, BFD enabled
```

```
R10#show ip ospf 181 | include BFD
    BFD is enabled
```

A quick check of the same routers shows similar results for OSPFv3 (assuming BFD is enabled for all interfaces). In this topology, CSR8 and CSR9 cannot be DR/BDR, and thus do not form BFD peers with one another. More accurately, because they do not form OSPF neighbors, the OSPF process does not inform BFD that a session should be created.

```
! CSR1, CSR8, CSR9, CSR10
router ospfv3 181
 address-family ipv6 unicast
  bfd all-interfaces
```

```
R1#show bfd neighbors client ospfv3
```

```
IPv6 Sessions
```

NeighAddr	LD/RD	RH/RS	State	Int
FE80::8	2/2	Up	Up	Gi2.518
FE80::9	1/2	Up	Up	Gi2.518
FE80::10	3/4	Up	Up	Gi2.518

```
R8#show bfd neighbors client ospfv3
```

```
IPv6 Sessions
```

NeighAddr	LD/RD	RH/RS	State	Int
FE80::1	2/2	Up	Up	Gi2.518
FE80::10	1/3	Up	Up	Gi2.518

```
R9#show bfd neighbors client ospfv3
```

```
IPv6 Sessions
```

NeighAddr	LD/RD	RH/RS	State	Int
FE80::1	2/1	Up	Up	Gi2.518
FE80::10	1/2	Up	Up	Gi2.518

```
R10#show bfd neighbors client ospfv3
```

```
IPv6 Sessions
```

NeighAddr	LD/RD	RH/RS	State	Int
FE80::1	4/3	Up	Up	Gi2.518
FE80::5	1/1	Up	Up	Gi2.550
FE80::8	3/1	Up	Up	Gi2.518
FE80::9	2/1	Up	Up	Gi2.518

Likewise, we check the OSPFv3 show commands to verify BFD is enabled.

```
R10#show ospfv3 neighbor 181.0.0.1 | include BFD
    In the area 0 via interface GigabitEthernet2.518, BFD enabled
```

```
R10#show ospfv3 interface gig2.518 | include BFD
    Transmit Delay is 1 sec, State DR, Priority 5, BFD enabled
```

```
R10#show ospfv3 181 | include BFD
    BFD is enabled
```

The output below shows that the echo feature is enabled using the timers we configured. This is an ideal configuration because the echoes are what make BFD lightweight on any router. From CSR9, we will look at CSR1 within the IPv4 AF. We see that OSPF is registered to BFD.

```
R9#show bfd neighbors ipv4 181.18.90.1 details | include ^Sess|^Regist
Session state is UP and using echo function with 900 ms interval.
Session Host: Software
Registered protocols: OSPF CEF
```

Interestingly, BFD echoes do not appear to be supported for IPv6 addresses. We will further reinforce this theory when we test BGP using non-LL addressing.

```
R8#show bfd neighbors ipv6 fe80::10 details | include echo
Session state is UP and not using echo function.
```

The BFD control packets are not lightweight like echoes and cannot be offloaded to hardware in all platforms. Below is a control packet on UDP port 3784 (0xEC8) and an echo on UDP port 3785 (0xEC9). The source UDP port for all BFD packets appears to be 49152 (0xC0000). The control ports are shown in cyan and the echo ports are shown in pink. The echo always has the source and destination IP set to the sender's address; this is done so the receiver can immediately loop the packet back out and not process it locally. The IP addressing is highlighted in green in both packets below. Notice the destination MAC of the echo is still CSR9's MAC which allows the frame to be delivered at layer 2, while the source is always CSR1's MAC (yellow/grey). The control packet is actually destined to CSR9 like a regular packet would and is punted to the CPU (RSP/RP) for processing.

```
R9#show interfaces gigabitEthernet 2 | include bia

```

We can confirm that we are receiving both echoes and control packets by counting the matches. **Note:** **uRPF and ICMP redirects must be disabled for echoes to work, for obvious reasons.** The router is smart enough to not send ICMP redirects even if you don't explicit disable it, but uRPF will break this feature.

```

R9#show monitor capture CAP buffer detailed | count 0EC8
Number of lines which match regexp = 64

```

```

R9#show monitor capture CAP buffer detailed | count 0EC9
Number of lines which match regexp = 140

```

We will simulate a failure on the LAN by configuring an inbound ACL on CSR8 to drop BFD echoes. We will debug BFD events on CSR8 to monitor the change. CSR8 shows the echo failure, notifies all of its clients, and then the OSPF neighbors fail. CSR8 has neighbors to CSR9/CSR10, the DR/BDR, so BFD tracks those.

```

! CSR8
ip access-list extended ACL_DENY_BFD_ECHO
deny    udp any any eq 3785
permit ip any any

```

```

interface GigabitEthernet2.518
ip access-group ACL_DENY_BFD_ECHO in

```

```

```

Removing the ACL, we see the sessions come back up. CSR8 can successfully receive BFD packets, and then initializes the BFD neighbor relationship. OSPF forms its neighbor first as it needs to tell BFD that it requests fast detection. When BFD comes up, it notifies OSPF that it can begin using BFD state.

```

```

A quick repeat of the same test, except filtering only the control traffic, yields similar results. BFD still does the exact same thing, except the failure event is based on not being able to detect a BFD peer at all. Losing echoes was a different failure event, but the result is identical. In most designs, the echo timer is much faster than the control timer, so a loss of control packets would take longer to discover. Upon failure, BFD notifies its clients who immediately tear down their neighbor sessions.

```
! CSR8

```

Upon restoration, the process is reversed, and when OSPF forms neighbors, it notifies BFD. When BFD completes its neighbor exchange, it notifies OSPF that it is now operational. This process is identical to the previous example in terms of debug and is not shown again. We quickly verify it using show commands.

```

R8#show bfd neighbors client ospf
IPv4 Sessions

```

NeighAddr	LD/RD	RH/RS	State	Int
181.18.90.9	4117/4109	Up	Up	Gi2.518
181.18.90.10	4118/4115	Up	Up	Gi2.518

Next, we look at BFD with IS-IS. The echo functionality was not explicitly enabled on the IS-IS LAN using the BFD-template construct. BFD makes no assumptions about your configuration when using templates; in this case, echoes are not used, so all of the BFD packets are control packets. If you use the "interval" command in a bfd-template without explicitly enabling "echo", only BFD control packets are affected by the timer specification. BFD still operates and is effective, but the lightweight behavior is reduced. Some high-end platforms can offload the entire BFD process to linecards, but echo offloading works on almost all routers since it is just based on routing. Despite having a DIS, IS-IS still forms neighbors will all nodes on the segment, or at least that is what IS-IS tells BFD to do. I also enable basic authentication, which is self explanatory. BFD dampening is like BGP or event dampening; continuous flaps will cause BFD to penalize an unstable neighbor. We do not analyze BFD dampening in detail since the logic is identical to BGP dampening (discussed in the security section).

```

! CSR1, CSR3, CSR4, CSR10
key chain KC_BFD_AUTH
key 1

```

```

key-string BFD_AUTH

bfd-template single-hop BFD_AUTH_DAMP
interval min-tx 900 min-rx 900 multiplier 3
authentication sha-1 keychain KC_BFD_AUTH
dampening 3 1500 3000 5

interface GigabitEthernet2.513
bfd template BFD_AUTH_DAMP

```

We can verify the “full mesh” of neighbors, as directed by IS-IS, and also verify that echoes are not enabled. Echoes must be enabled bidirectionally in order for BFD to negotiate them. Also notice that since IS-IS works with both IPv4 and IPv6, we can see the IPv6 peers by checking the IS-IS clients. For brevity, I just show CSR1 and CSR3, but the neighbors are fully meshed.

```

R1#show bfd neighbors client isis
IPv4 Sessions

```

```

```
R10#show clns interface gig2.513 | include BFD
```

```
  BFD enabled: (MTID:0, ipv4) (MTID:2, ipv6)
```

A quick look at CSR3's capture shows only packets with varying source/destination addresses. If there were many echoes, we would see packets destined to themselves at layer 3 arriving on CSR3's interface from the other 3 routers on the segment. We see no such packets, which is a good indication that BFD echoes are not enabled on this LAN segment.

```
R3#show monitor capture CAP buffer brief
```

#	size	timestamp	source		destination	protocol
0	98	0.000000	181.13.40.1	->	181.13.40.10	UDP
1	98	0.009002	181.13.40.10	->	181.13.40.1	UDP
2	98	0.020995	181.13.40.4	->	181.13.40.10	UDP
3	98	0.033995	181.13.40.1	->	181.13.40.10	UDP
4	98	0.041990	181.13.40.4	->	181.13.40.10	UDP
5	98	0.042997	181.13.40.1	->	181.13.40.3	UDP
6	98	0.050001	181.13.40.4	->	181.13.40.1	UDP
7	98	0.057996	181.13.40.10	->	181.13.40.1	UDP
8	98	0.069989	181.13.40.3	->	181.13.40.10	UDP
9	98	0.077999	181.13.40.3	->	181.13.40.1	UDP
10	98	0.085994	181.13.40.10	->	181.13.40.1	UDP

11	98	0.100993	181.13.40.1	->	181.13.40.10	UDP
12	98	0.108988	181.13.40.3	->	181.13.40.10	UDP
13	98	0.116998	181.13.40.10	->	181.13.40.1	UDP
14	98	0.124994	181.13.40.3	->	181.13.40.1	UDP

We can also use output filtering to help prove the point. Searching for the hexadecimal control-port in the packet details, we have many hits. Searching for the echo port yields zero hits.

```
R3#show monitor capture CAP buffer detail | count 0EC8
Number of lines which match regexp = 924
```

```
R3#show monitor capture CAP buffer detail | count 0EC9
Number of lines which match regexp = 0
```

A quick detailed look at one of the packets clearly shows it is a control packet. This particular packet was sent from CSR1 to CSR3.

```

```

We will correct this behavior using HSRP and PIM next. Enabling "echo" in the template on CSR3 and CSR4 for the VPN session sends echoes. CSR2 also has it enabled. Adjusting the "slow-timer" to 5 seconds, we can slow down the rate at which we send control messages. The timers are shown within the details and are different than the echo timer. The default slow-timer for control messages is 1 second, which is close to our BFD echo timer of 900 ms. We also configure basic HSRP for IPv4 and IPv6 within this VPN so that HSRP can be bound to BFD. HSRP can re-use the BFD key-chain, as can EIGRP. As a final touch, PIM is enabled also, just to demonstrate that it too can register to BFD.

```
! CSR3, CSR4
key chain KC_GEN_AUTH
key 1
key-string GEN_AUTH

bfd slow-timers 5000

bfd-template single-hop BFD_ECHO_VPN
interval min-tx 900 min-rx 900 multiplier 3
```

```

 bfd template BFD_ECHO_VPN

```

We quickly verify that CSR3 and CSR4 see two peers each, one another and CSR2. We also verify echoes have been negotiated as expected with a 5 second control-message (slow-timer) interval. We can see that EIGRP, HSRP, and PIM are bound to BFD for both IPv4 and IPv6 successfully. Again, we see that the echo function does not appear to be supported for IPv6 LL addressing. Because of this, the TX/RX intervals are 900ms, not 5000ms, since the control messages are actually used for dead peer detection.

The slow-timer only applies to control messages when echoes are negotiated.

```

R3#show bfd neighbors vrf L3 client pim ipv4 details | include
^Sess|^Regist|xInt
Session state is UP and using echo function with 900 ms interval.
Session Host: Software

FE80::4

Active groups: 236

No standby groups

BFD enabled

Capturing for about 10 seconds on CSR3's VPN interface, we can capture the control messages. Since we know echoes have the same IPv4 source/destination, we can assume that traffic going to CSR3 from CSR4 (or CSR2) is not an echo. The output below shows the control packets from CSR4 to CSR3 over that period. The time between them is about 4 seconds, which is close enough to the timer we configured.

```
R3#show monitor capture CAP buffer brief | include 10.23.4.4.*10.23.4.3
 83   94   1.689011  10.23.4.4    ->  10.23.4.3    UDP
302   94   5.766018  10.23.4.4    ->  10.23.4.3    UDP
543   94   9.755017  10.23.4.4    ->  10.23.4.3    UDP
```

The vast majority of packets are echoes. The promiscuous ESXi port-groups show all of the echoes on the LAN, but the point is that we have reduced the control traffic while still keeping performance good and convergence fast.

```
R3#show monitor capture CAP buffer brief
-----
#    size  timestamp      source          destination    protocol

```

Now that we understand echoes and control packets, we will examine the actual timer values between CSR5 and CSR10 before continuing. Many others have suggested that the naming of these timers is difficult to interpret, and it is. The number following the “bfd interval” command is the “min_tx” value, followed by “min_rx”. When exchanging control packets, the potential BFD peers exchange these values (just like HSRP). The local min_tx is compared against the received min_rx from the peer. The larger (slower) value wins and is used as the hello interval from the local router. This is a unidirectional timer and may vary in both directions. Below, CSR5 has its min_tx timer set to 910 ms and its min_rx timer set to 890 ms. CSR10 uses values 900 and 920 for min_tx and min_rx, respectively.

```
! CSR5
interface GigabitEthernet2.550
  bfd interval 910 min_rx 890 multiplier 3
```

```
! CSR10
interface GigabitEthernet2.550
  bfd interval 900 min_rx 920 multiplier 3
```

From CSR5's perspective, its local min_tx (910) is compared to CSR10's min_rx (920) to determine how quickly it should send hellos. Since CSR9 is not willing to accept hellos any faster than 920ms, CSR5 will use a value of 920. Note that the "TxInt" and "RxInt" timers in the output below do not represent the echo timers; these are for the control packets discussed earlier.

```
R5#show bfd neighbors ipv4 181.5.10.10 details | include echo|xInt
Session state is UP and using echo function with 920 ms interval.
MinTxInt: 1000000, MinRxInt: 1000000, Multiplier: 3
Received MinRxInt: 1000000, Received Multiplier: 3
```

In the opposite direction, CSR9 compares its local min_tx (900) to CSR5's min_rx (890). Since CSR9 cannot send any faster than 900ms, this value is used.

```
R10#show bfd neighbors ipv4 181.5.10.5 details | include echo|xInt
Session state is UP and using echo function with 900 ms interval.
MinTxInt: 1000000, MinRxInt: 1000000, Multiplier: 3
Received MinRxInt: 1000000, Received Multiplier: 3
```

We can manually disable echoes on this link between CSR5 and CSR10. To be a minimalist, I will only disable echoes on CSR5, which has the added benefit of disabling echoes for anything trying to establish BFD sessions with CSR5. We also look at the "Hello" value since this is the result of the local min_tx versus remote min_rx comparison. CSR5 selects 920 ms, which is CSR10's min_rx, since it is greater than its local min_tx. CSR10 selects 900 ms, which is its local min_tx, since it is greater than CSR5's remote min_rx. Because echoes were disabled, the "TxInt" and "RxInt" timers now reflect the configured intervals. As mentioned earlier, using control packets for dead peer detection generally undesirable as echoes are lighter weight.

```
! CSR5
interface GigabitEthernet2.550
  no bfd echo
```

```
R5#show bfd neighbors ipv4 181.5.10.10 details | include echo|xInt|Hello
Session state is UP and not using echo function.
MinTxInt: 910000, MinRxInt: 890000, Multiplier: 3
Received MinRxInt: 920000, Received Multiplier: 3
Holddown (hits): 2061(0), Hello (hits): 920(6600)
```

```
R10#show bfd neighbors ipv4 181.5.10.5 details | include echo|xInt|Hello
Session state is UP and not using echo function.
MinTxInt: 900000, MinRxInt: 920000, Multiplier: 3
Received MinRxInt: 890000, Received Multiplier: 3
Holddown (hits): 2196(0), Hello (hits): 900(6623)
```

Next, we will examine BFD multi-hop sessions, which carry some additional restrictions. RFC 5883 states that the echo function must not be used over multi-hop BFD sessions. This is because the intermediate hops would route the packets directly back to the source, so only control packets exist using port 4784 (0x12B0) are shown below. You cannot configure BFD echoes on a template applied to a multi-hop session. Below is a capture inbound on CSR9 to see the BFD packets from CSR5. I would assume this means that BFD for pseudowires, when used in this way, is generally undesirable unless the platform can hardware-offload the packets. BFD can run inside VCCV in some versions/platforms, but not the CSR1000v. The BFD-map command assigns a template to a specific source/destination pair in a specified VRF (as needed). When a BFD session is established that matches a BFD-map, the longest-match rules apply, and a template is used to build the BFD session. I use interesting masks in this example just to illustrate the point, but using /32s for explicit multi-hop links is the most straightforward. The significant benefit of multi-hop sessions is that it allows BFD to track layer 3 paths, not just layer 2 paths.

```
! Both CSR5 and CSR9
bfd-template multi-hop BFD_L2VPN
  interval min-tx 900 min-rx 900 multiplier 3

template type pseudowire TMP_VPLS
  encapsulation mpls
  control-word include
  signaling protocol ldp

l2vpn vfi context VPLS
  autodiscovery bgp signaling ldp template TMP_VPLS

! CSR5 only
bfd map ipv4 181.0.0.0/28 181.0.0.0/29 BFD_L2VPN

template type pseudowire TMP_VPLS
  monitor peer bfd local interface Loopback0

! CSR9 only
bfd map ipv4 181.0.0.5/32 181.0.0.9/32 BFD_L2VPN

template type pseudowire TMP_VPLS
  monitor peer bfd
```

The verification process for this is two steps. First, we need to verify the BFD neighbor is up and that xconnect is registered to it. Then, we will verify that the PW details include BFD state information.

```
R9#show bfd neighbors multihop-ipv4 181.0.0.5 details | include ^Sess|^Regist
Session state is UP and not using echo function.
Session Host: Software
Registered protocols: Xconnect
```

```
R9#show l2vpn atom vc vcid 1112 detail | include BFD
Fast failure detection (BFD): up
  BFD dataplane status received      : Not sent
  BFD peer monitor status received   : No fault
```

We can check each BFD-map for a list of BFD neighbors that are using the map attributes. Show/debug commands indicate that the “L” and “R” stand for local and remote, respectively, and the “D” stands for “discriminator”. The numbers are reversed on either side of the BFD peering and the BFD-map references the LD when describing the sessions that inherit from it.

```
R9#show bfd map internal
Destination[vrf]: 181.0.0.5/32
Source[vrf]: 181.0.0.9/32
Template: BFD_L2VPN
Authentication(Type/Keychain): invalid_type/
Adjacencies associated to map:
  LD: 4111, Ref: 0x7F8A337A9600
```

```
R9#show bfd neighbors multihop-ipv4
IPv4 Multihop Sessions
NeighAddr[vrf]          LD/RD          RH/RS          State
181.0.0.5              4111/4100        Up             Up
```

We can verify this is true by checking the other side as well. We see that 4111 is CSR9’s LD which maps to CSR5’s RD. The opposite is true for the value 4100 (LD of CSR5, RD of CSR9).

```
R5#show bfd map internal
Destination[vrf]: 181.0.0.0/28
Source[vrf]: 181.0.0.0/29
Template: BFD_L2VPN
Authentication(Type/Keychain): invalid_type/
Adjacencies associated to map:
  LD: 4100, Ref: 0x7FB78F42DE10
```

```
R5#show bfd neighbors multihop-ipv4
IPv4 Multihop Sessions
NeighAddr[vrf]          LD/RD          RH/RS          State
181.0.0.9              4100/4111        Up             Up
```

The BFD session for this PW is just a normal IP/UDP flow between two endpoints. The end router sees it as IP, not MPLS, simply because the penultimate hop performs PHP. This is different than the VCCV-based BFD (not supported on CSR1000v) which would be carried in the PW-ACH, implying MPLS encapsulation from end-to-end.

```
R9#monitor capture CAP match ipv4 protocol udp 181.0.0.5/32 181.0.0.9/32 eq
4784
```

```

R9#show monitor capture CAP buffer detailed
 14   70   0.394029  181.0.0.5    ->  181.0.0.9    UDP
0000:  005056A9 D6720050 56A9F961 81000DBE  .PV..r.PV..a....
0010:  080045C0 00340C51 0000FE11 4599B500  ..E...4.Q....E...

0030:  03180000 10020000 1005000D BBA0000D  .....

```

We can simulate a failure by blocking these multi-hop BFD packets in the transit path. I will do it on CSR9 once all the MPLS transport labels are removed, revealing the IP packet.

```

! CSR9
ip access-list extended ACL_DENY_MHOP_BFD
deny  udp any any eq 4784
permit ip any any

interface GigabitEthernet2.518
ip access-group ACL_DENY_MHOP_BFD in

```

Debugging AToM status events on CSR5, we can see that there is a fault with sending messages to CSR9. CSR5 generates a status message to show this, as does CSR9. Both routers update their PW status to down due to a fast failure detection (FFD) error, a sub-process within the PW process. The Cisco documentation does not detail what the “A” means in the state machine, but I assume it is some kind of administrative hold-down on the PW due to a sub-process like FFD dictating the PW remain down. It could also mean “active” since BFD keeps trying to re-establish the session so long as it has a client.

```

R5#debug l2vpn atom vc status event
AToM[181.0.0.9, 1112]:  FFD          : DOWN(pw-tx-fault)
AToM[181.0.0.9, 1112]:  .. FFD          : DOWN(pw-tx-fault)
AToM[181.0.0.9, 1112]:  .. Overall      : DOWN(pw-rx-fault)
AToM[181.0.0.9, 1112]:  .. Update AC for status change from UP
AToM[181.0.0.9, 1112]:  .. Send AC STATUS (DOWN(pw-rx-fault))
AToM[181.0.0.9, 1112]:  .. Send notify(DOWN)
AToM[181.0.0.9, 1112]:  .. FFD          : DOWN(pw-tx-fault)
AToM[181.0.0.9, 1112]:  .. Overall      : DOWN(pw-tx-fault)
[snip]
%XCONNECT-5-PW_STATUS: MPLS peer 181.0.0.9 vcid 1112, VC state DOWN, PW Err

```

```

R5#show l2vpn atom vc vcid 1112 detail | include BFD
Fast failure detection (BFD): down
BFD dataplane status received          : Not sent
BFD peer monitor status received        : DOWN(pw-tx-fault)

```

```

R5#show l2vpn atom vc vcid 1112 detail | include state_machine
Label/status state machine              : established, LruRrA

```

We see similar output on CSR9. Both routers think there is a TX problem with the remote end since the issue is in the transit path, not related to a local AC.

```

R9#show l2vpn atom vc vcid 1112 detail | include BFD
Fast failure detection (BFD): down
  BFD dataplane status received      : Not sent
  BFD peer monitor status received   : DOWN(pw-tx-fault)

R9#show l2vpn atom vc vcid 1112 detail | include state_machine
Label/status state machine          : established, LruRrA

```

Before continuing, we will remove the ACL from CSR9. With debugging still enabled on CSR5, we can see the FFD process shows no fault and brings the PW back online.

```

! CSR5
AToM[181.0.0.9, 1112]: FFD      : No fault
AToM[181.0.0.9, 1112]: .. Remote   : DOWN(pw-tx-fault)

Label/status state machine          : established, LruRru

```

BGP can also use BFD in single or multi-hop fashion. Multi-hop BFD does not appear to work with IPv6 though, so we will use multi-hop for IPv4 and single-hop for IPv6 between CSR7 (CE) and CSR8 (PE). Because echoes are not supported on any kind of multi-hop connections, I will enable them for the IPv6 single-hop connection. The reason for enabling BGP graceful restart (GR) and the check-control-plane failure (C-bit) are described later.

```

! CSR7 and CSR8
key chain KC_MHOP
  key 1
    key-string MHOP

bfd-template multi-hop BFD_MHOP
  interval min-tx 900 min-rx 900 multiplier 3
  authentication meticulous-sha-1 keychain KC_MHOP

bfd-template single-hop BFD_SHOP

```

```

interval min-tx 900 min-rx 900 multiplier 3
authentication meticulous-sha-1 keychain KC_MHOP
echo

! CSR8 only
bfd map ipv4 vrf L3 7.7.7.7/32 vrf L3 10.7.8.8/32 BFD_MHOP

router bgp 181
  bgp graceful-restart
  address-family ipv4 vrf L3
    neighbor 7.7.7.7 disable-connected-check
    neighbor 7.7.7.7 fall-over bfd multi-hop check-control-plane-failure

address-family ipv6 vrf L3
  neighbor FD00:10:7:8::7 fall-over bfd single-hop

ip route vrf L3 7.7.7.7 255.255.255.255 GigabitEthernet2.578 10.7.8.7

! CSR7 only
bfd map ipv4 10.7.8.8/32 7.7.7.7/32 BFD_MHOP

router bgp 7
  bgp graceful-restart
  neighbor 10.7.8.8 fall-over bfd multi-hop check-control-plane-failure
  neighbor FD00:10:7:8::8 fall-over bfd single-hop

```

We can check to ensure the sessions are up from CSR8 within the VRF. Neither session is using echoes; for the third time, we have seen a lack of echo support for IPv6 despite being configured for it. We can also verify that BGP is registered to BFD properly. The multi-hop session does not register CEF as a client since the lookup is recursive.

```

R8#show bfd neighbors multihop-ipv4 vrf L3 7.7.7.7 details | include
^Sess|^Regist
Session state is UP and not using echo function.
Session Host: Software
Registered protocols: BGP

R8#show bfd neighbors vrf L3 ipv6 FD00:10:7:8::7 details | include
^Sess|^Redist
Session state is UP and not using echo function.
Session Host: Software
Registered protocols: BGP CEF

```

We can quickly check BGP to ensure BFD is configured for this peer. CSR8 has it within VPNv4 (a customer VRF) and CSR7 has it in the global IPv4 unicast AFI. I cannot explain why CSR8 doesn't show that the BFD session is up or why the C-bit check is not displayed, because they are operational. I assume this is a cosmetic decision specific to the VPNv4 show command.

```
R8#show bgp vpnv4 unicast vrf L3 neighbors 7.7.7.7 | include BFD
BFD is configured.
```

```
R7#show bgp ipv4 unicast neighbors 10.7.8.8 | include BFD
BFD is configured. BFD peer is Up. Using BFD to detect fast fallover (multi-hop) with c-bit check-control-plane-failure.
```

For completeness, we can check the LD/RD and BFD map information. CSR7 has an LD of 4098 which is used to create a neighbor to CSR8. CSR8 sees that LD as its RD.

```
R7#show bfd neighbors multihop-ipv4 10.7.8.8
IPv4 Multihop Sessions
NeighAddr[vrf]                LD/RD                RH/RS                State
10.7.8.8                      4098/4099                Up                    Up
```

```
R7#show bfd map internal
Destination[vrf]: 10.7.8.8/32
Source[vrf]: 7.7.7.7/32
Template: BFD_MHOP

Authentication keys:
  Send - ID: 1, String: MHOP
  Accept - ID: 1, String: MHOP
Adjacencies associated to map:
  LD: 4098, Ref: 0x7F4015FEBAC8
```

```
R8#show bfd neighbors multihop-ipv4 vrf L3 7.7.7.7
IPv4 Multihop Sessions
NeighAddr[vrf]                LD/RD                RH/RS                State
7.7.7.7 [L3]                  4099/4098                Up                    Up
```

With BFD properly configured, we will examine the C-bit and its significance. This is neither straightforward nor well-documented. First, we will ensure the GR capability was exchanged PE-CE. BGP GR is covered in detail in the High Availability (HA) section.

```
R7#show bgp ipv4 unicast neighbors 10.7.8.8 | include Grace
Graceful Restart Capability: advertised and received
Graceful-Restart is enabled, restart-time 120 seconds, stalepath-time 360 seconds
```

```
R8#show bgp vpnv4 unicast vrf L3 neighbors 7.7.7.7 | include Grace
Graceful Restart Capability: advertised and received
Graceful-Restart is enabled, restart-time 120 seconds, stalepath-time 360 seconds
```

The BFD process can set the C-bit, or control-plane bit (not to be confused with the PW C-bit, or control-word bit). The C-bit will be set to 0 when BFD is run in software or 1 when it runs in hardware on a linecard. This allows your BFD peer to determine whether or not a failure of BFD control traffic is really an indication of a node failure. For example, if a node stops receiving BFD control packets and the peer's C-bit is 0, it is safe to assume that BFD was not running on the linecard, and maybe the RSP was restarted. The linecard can continue passing traffic, which is the basis of non-stop forwarding (NSF). BFD does not instruct BGP to purge routes since the data-plane is still operable. If a node stops receiving BFD control packets and the C-bit is 1, this means the entire BFD process was running on that linecard, so chances are the whole linecard is inoperable. BFD will instruct BGP to purge all routes in this case. CSR1000v does not have separate RSPs and linecards (BFD runs in software) so the C-bit should remain zero. By default, BGP totally ignores this bit, and the "check-control-plane-failure" option tells BGP to look at it. This can prevent black holes when the linecard actually does fail at the same time the RSP does. BFD tracks the last control packet's information; we can see the C-bit is zero for reasons already described. Also note "my/your" values the session discriminators seen earlier.

```
R8#show bfd neighbors multihop-ipv4 vrf L3 7.7.7.7 details | begin Last_pack
Last packet: Version: 1                - Diagnostic: 0
          State bit: Up                - Demand bit: 0
          Poll bit: 0                  - Final bit: 0
          C bit: 0
          Multiplier: 3                - Length: 52
          My Discr.: 4098              - Your Discr.: 4099
          Min tx interval: 900000      - Min rx interval: 900000
          Min Echo interval: 0
```

This feature is also supported in IS-IS. I enable it on CSR3 and CSR4, although no show commands seem to exist to verify it. Considering all BFD sessions thus far have been in "software", the C-bit doesn't mean much and will always be zero on the CSR1000v.

```
! CSR3 and CSR4
router isis 181
  bfd check-ctrl-plane-failure
```

Back to BGP, we will test IPv6 between CSR7 and CSR8. We already verified that BFD sees BGP as a client for IPv6. We quickly verify this using BGP show commands on both CSR7 and CSR8.

```
R8#show bgp vpv6 unicast vrf L3 neighbors FD00:10:7:8::7 | include BFD
BFD is configured. BFD peer is Up. Using BFD to detect fast fallover
(single-hop).
```

```
R7#show bgp ipv6 unicast neighbors FD00:10:7:8::8 | include BFD
BFD is configured. BFD peer is Up. Using BFD to detect fast fallover
(single-hop).
```

We will use an IPv6 ACL to drop single-hop BFD control packets for IPv6, which should break the eBGP connection to CSR8. We also enable BFD event and BGP IPv6 unicast debugging. When CSR7 cannot receive control packets anymore, it cannot detect CSR8, and tears down the BFD session. It notifies all clients (BGP and CEF in this case) that the session is down.

```

BGP keeps track of these failures on a per-neighbor basis. We can see both CSR7 and CSR8 claim that BFD was the reason for the last peer failure.

```
R8#show bgp vpnv6 unicast vrf L3 neighbors FD00:10:7:8::7 | include BFD
```

BFD is configured. BFD peer is Up. Using BFD to detect fast fallover (single-hop).

Last reset 00:11:13, due to BFD adjacency down of session 1

```
R7#show bgp ipv6 unicast neighbors FD00:10:7:8::8 | include BFD
```

BFD is configured. BFD peer is Up. Using BFD to detect fast fallover (single-hop).

Last reset 00:11:43, due to BFD adjacency down of session 1

BFD can also support static routes. The sessions cannot be used on PPPoE (dialer/virtual-template) interfaces but are supported on most other interface types. This is one of the most complicated BFD configurations, especially because the parser is inconsistent. It appears that only multi-hop sessions are available when using this inside VRFs for IPv4, so we will have to create multi-hop sessions from CSR5 to CSR6 despite them being connected. This means we need a multi-hop template and a BFD-map for the endpoints. We can make a very generic BFD map such that the endpoint matching (10.0.0.0/8) identical for both nodes. The only difference will be the presence of a VRF on CSR5. The routes in CSR5 are VRF aware while those in CSR6 are not. CSR5 has two VRF routes to reach remote CE networks and redistributes these into BGP for L3VPN service. BFD tracks the next-hop of those routes. One entry is marked as passive; this does not establish a BFD session, but simply tracks the non-passive one. If 10.5.6.6 becomes unavailable, it is assumed that 10.5.6.66 is also unavailable (in this case, a secondary address). Both the 10.6.6.6/32 and 10.66.66.66/32 routes can be withdrawn without having to use a different BFD peer per next-hop or per static route. CSR6 has a simplified configuration with just a default route to the next-hop, which is BFD tracked. **Pitfall: When using multi-hop static route sessions, you must never include the outgoing interface in the static route, only the IP addresses. For single-hop static route sessions, you must always include the outgoing interface in the static route.**

```
! CSR5
bfd-template multi-hop BFD_STATIC
  interval min-tx 900 min-rx 900 multiplier 3
  echo

bfd map ipv4 vrf L3 10.0.0.0/8 vrf L3 10.0.0.0/8 BFD_STATIC

ip route static bfd vrf L3 10.5.6.66 vrf L3 10.5.6.5 group L3_GROUP passive
ip route vrf L3 10.6.6.6 255.255.255.255 10.5.6.6
ip route vrf L3 10.66.66.66 255.255.255.255 10.5.6.66

! CSR6
bfd-template multi-hop BFD_STATIC
  interval min-tx 900 min-rx 900 multiplier 3
  echo

bfd map ipv4 10.0.0.0/8 10.0.0.0/8 BFD_STATIC

ip route static bfd 10.5.6.5 10.5.6.6 log
```

```
ip route 0.0.0.0 0.0.0.0 10.5.6.5
```

The “log” keyword will generate log messages when the reachability status changes. This is useful for static routing since there is no IGP/BGP to generate logs for us. Flapping CSR6’s interface shows the down and up log messages. Despite configuring echo, the feature cannot work since technically this is a multi-hop session. There is no good reason why single-hop functionality is not available in a VRF (but is in the global table); this is the only reason we used a multi-hop session.

```
! CSR6
%IPRT-5-STATICROUTES_BFD_EVENT: BFD session Down, [Destination

```

```
R6#show bfd neighbors client static-v4 details | include ^Sess|^Regist
Session state is UP and not using echo function.
Session Host: Software
Registered protocols: IPv4 Static
```

There is an entirely new set of show commands we can use to verify this as well. Since the ordinary “show ip route” command doesn’t reveal anything new, there has to be a way to verify BFD from the perspective of the supported client protocol. The commands below reveal more detail about the origin of a static route. They can end up in the RIB for a number of reasons: AAA, DHCP, PFR (OER), PPP, MPLS-TE (auto-route destination), etc. It is nice to see this kind of detail when troubleshooting “phantom” static routes. In this case, they are manually configured and tracked by BFD.

```
R5#show ip static route vrf L3
Codes: M - Manual static, A - AAA download, N - IP NAT, D - DHCP,
       G - GPRS, V - Crypto VPN, C - CASA, P - Channel interface processor,
       B - BootP, S - Service selection gateway
       DN - Default Network, T - Tracking object
       L - TL1, E - OER, I - iEdge
       D1 - Dot1x Vlan Network, K - MWAM Route
       PP - PPP default route, MR - MRIPv6, SS - SSLVPN
       H - IPe Host, ID - IPe Domain Broadcast
       U - User GPRS, TE - MPLS Traffic-eng, LI - LIIN
       IR - ICMP Redirect
Codes in [: A - active, N - non-active, B - BFD-tracked, D - Not Tracked, P
- permanent
Static local RIB for L3
M 10.6.6.6/32 [1/0] via 10.5.6.6 [AB]
M 10.66.66.66/32 [1/0] via 10.5.6.66 [AB]
```

```
R5#show ip static route bfd
Codes in [: R - Reachable, U - Unreachable, L - Loop, D - Not Tracked
IPv4 Static BFD Multihop Sessions:
Destination [vrf] : 10.5.6.6 [L3]
```

```
Source [vrf]      : 10.5.6.5      [L3]
Status           : [R]
Group Info       : L3_GROUP, Active
```

```
Destination [vrf] : 10.5.6.66     [L3]
Source [vrf]      : 10.5.6.5      [L3]
Status           : [R]
Group Info       : L3_GROUP, Passive
```

We can verify this on CSR6 also. The output is basically the same, except there is only one default route and no assigned association group.

```
R6#show ip static route | begin Static
Static local RIB for default
M 0.0.0.0/0 [1/0] via 10.5.6.5 [AB]
```

```
R6#show ip static route bfd 10.5.6.5
Codes in []: R - Reachable, U - Unreachable, L - Loop, D - Not Tracked
IPv4 Static BFD Multihop Sessions:
Destination [vrf] : 10.5.6.5
Source [vrf]      : 10.5.6.6
Status           : [R]
Group Info       :
```

From CSR5, we currently have both routes in the VRF table, meaning they are “active”. By creating an ACL on CSR6 to block the BFD control messages (echoes are not in use), this will break the BFD session and should withdraw both routes. Even though there isn’t a BFD session to 10.5.6.66, it is associated to a route that does have a BFD session and shares its fate.

```
R5#show ip route vrf L3 static | begin Gate
Gateway of last resort is not set
    10.0.0.0/8 is variably subnetted, 5 subnets, 2 masks
S      10.6.6.6/32 [1/0] via 10.5.6.6
S      10.66.66.66/32 [1/0] via 10.5.6.66
```

Debugging BFD and VRF-aware RIB changes, we apply the ACL to CSR6 to drop the BFD multi-hop control packets. BFD detects the failure and notifies “IPv4 Static” that the session failed. BFD generates a syslog message, and the RIB removes both 10.6.6.6/32 and 10.66.66.66/32 routes as a result of the failure.

```
! CSR6
ip access-list extended ACL_DENY_BFD_CONTROL
deny   udp any any eq 4784
permit ip any any

```

With the routes withdrawn, we can see the “A” for active turns into an “N” for non-active. These don’t show up in the RIB, but rather than search for them in the configuration, we can see them here at all times. Using IP SLA to track static routes would be comparable to using a protocol-specific hello timer; BFD is the newer and better option when static routes are configured bidirectionally.

```

R5#show ip static route vrf L3 | begin Codes_in
Codes in []: A - active, N - non-active, B - BFD-tracked, D - Not Tracked, P
- permanent
Static local RIB for L3
M 10.6.6.6/32 [1/0] via 10.5.6.6 [NB]

R5#show ip route vrf L3 static | begin Gateway
Gateway of last resort is not set
[no output]

```

Unlike the IGP, IPv4 Static can’t tell BFD when it comes back (no discovery mechanism), so BFD is in charge of telling IPv4 Static to go up and go down. The process is similar on CSR5 when we remove the ACL from CSR6, the only similarity to the IGP being that the BFD session comes fully “up” once the routes get added to the RIB. BFD went fully down when the routes were removed from the RIB also, seen earlier.

```

BFD-DEBUG Event: V1 FSM ld:4102 handle:4 event:RX UP state:UP (0)
```

Last, we examine IPv6 static routing with BFD. Interestingly, single-hop seems to be supported for IPv6 as we can specify an interface when selecting the VRF-aware option. Multi-hop is not even an option though, so the feature options between IPv4/v6 static are mutually exclusive (IPv4 multi-hop or IPv6 single-hop). We also don't have the fancy group configuration or logging features available for IPv6 Static. Otherwise, the configuration is very similar and does not warrant additional explanation. Notice that we must include the outgoing interface with the static routes since these are single-hop BFD peers; including the outgoing interface with multi-hop BFD peers results in a broken configuration.

```
! CSR5
ipv6 route static bfd vrf L3 GigabitEthernet2.556 FE80::6
ipv6 route vrf L3 ::10:6:6:6/128 GigabitEthernet2.556 FE80::6
ipv6 route vrf L3 ::10:66:66:66/128 GigabitEthernet2.556 FE80::6

! CSR6
ipv6 route static bfd GigabitEthernet2.556 FE80::5
ipv6 route ::/0 GigabitEthernet2.556 FE80::5
```

Suddenly, this session claims to be running in “hardware”, which is the first time I’ve seen this. Even stranger is that because this is supported in “hardware”, the C-bit is set, which one would expect if this was actually true (it obviously isn’t on a CSR1000v). The C-bit functionality and purpose was discussed in the BGP section.

```
R5#show bfd neighbors ipv6 fe80::6 details | include ^Sess|^Regist
Session state is UP and not using echo function.
Session Host: Hardware

```

We can see IPv6 static routing is bound to this BFD neighbor on CSR5. We can also check the static routing details to see the two routes tracked by BFD.

```
R5#show ipv6 static vrf L3 bfd
```

IPv6 Static BFD Neighbors (Table - L3)

Codes: * - installed in RIB, u/m - Unicast/Multicast only
U - Per-user Static route, N - ND Static route
P - DHCP-PD Static route

Neighbor FE80::6/GigabitEthernet2.556 [Up]

```
* ::10:66:66:66/128 via FE80::6, GigabitEthernet2.556, distance 1
* ::10:6:6:6/128 via FE80::6, GigabitEthernet2.556, distance 1
```

R5#show ipv6 route vrf L3 static | begin ^S

```
S ::10:6:6:6/128 [1/0]
    via FE80::6, GigabitEthernet2.556
S ::10:66:66:66/128 [1/0]
    via FE80::6, GigabitEthernet2.556
```

Using the same mechanism as before, we will create an IPv6 ACL to block UDP port 3784, killing the BFD single-hop control traffic. Be sure not to confuse the single-hop and multi-hop ports.

```
! CSR6
ipv6 access-list ACL_DENY_BFD_CONTROL_V6
deny udp any any eq 3784
permit ipv6 any any

interface GigabitEthernet2.556
ipv6 traffic-filter ACL_DENY_BFD_CONTROL_V6 in
```

Debugging on CSR5 reveals very similar output with IPv6 as it did for IPv4. The only difference is that there is no syslog message generated since the feature is not supported for IPv6.

```
R5#debug bfd event
R5#debug ipv6 routing
BFD-DEBUG Event: V1 FSM ld:3 handle:5 event:RX DOWN state:UP (0)
BFD-DEBUG Event: resetting timestamps ld:3 handle:5 (0)
BFD-DEBUG Event: notify client(CEF) IP:FE80::6, ld:3, handle:5, event:DOWN,
cp independent failure (0)
BFD-DEBUG Event: notify client(IPv6 Static) IP:FE80::6, ld:3, handle:5,
event:DOWN, cp independent failure (0)
[IPv6 Static Handler]IPv6RT[L3]: static, Delete next-hop for
::10:66:66:66/128, FE80::6%L3, GigabitEthernet2.556%L3
[IPv6 Static Handler]IPv6RT[L3]: static, Delete ::10:66:66:66/128 from table
[IPv6 Static Handler]IPv6RT[L3]: static, Delete next-hop for ::10:6:6:6/128,
FE80::6%L3, GigabitEthernet2.556%L3
[IPv6 Static Handler]IPv6RT[L3]: static, Delete ::10:6:6:6/128 from table
[IPv6 RIB Event Handler]IPv6RT[L3]: Event: ::10:66:66:66/128, Del, owner
static, previous None
[IPv6 RIB Event Handler]IPv6RT[L3]: Event: ::10:6:6:6/128, Del, owner static,
previous None
BFD-DEBUG Event: V1 FSM ld:3 handle:5 event:RX DOWN state:DOWN (0)
```

The BFD session is down, so we don't expect to see those routes in the VRF RIB anymore. The IPv6 output doesn't have as many flags as IPv4, but it clearly shows the BFD session as being down. This implies that the routes should not be active in the RIB. The removal of the "*" seen on the routes (left side of the screen) earlier is an indication that these routes are not installed in the RIB; we verify that they are absent.

```
R5#show ipv6 static vrf L3 bfd | begin ^Neighbor
Neighbor FE80::6/GigabitEthernet2.556 [Down]
      ::10:66:66:66/128 via FE80::6, GigabitEthernet2.556, distance 1
      ::10:6:6:6/128 via FE80::6, GigabitEthernet2.556, distance 1
```

```
R5#show ipv6 route vrf L3 static | begin ^S
[no output]
```

The process is very similar in the opposite direction as one would expect. When BFD starts receiving packets again, it notifies IPv6-static so the routes can be re-added to the RIB. Once that is complete, BFD comes fully up.

```

```

Additional Reading – Reference configurations "bfd"

41. Describe, implement, and troubleshoot control plane protection techniques

41.1 Control Plane Policing (CPP) in XE and Local Packet Transport Services (LPTS) in XR

CPP and LPTS are generally used to treat traffic destined to or originating from the router itself. This "treat" action is typically policing or dropping, but can also be QoS marking (for outbound traffic). CPP uses the standard MQC syntax and the policies can be applied inbound or outbound on the router's control-plane "subinterfaces". LPTS configuration is more like a stateless host firewall in which certain

exceptions are made dynamically as new features are configured. The network diagram below shows 4 MPLS routers servicing 4 remote sites. CSR7 represents a shared services site, like the Internet, while the other three CEs are part of an internal VPN. Different PE-CE routing protocols are used intentionally to test different CPP/LPTS filtering policies. CSR9 represents a management laptop that has an out-of-band network to reach each router. The 8 “production” routers in this lab have a separate VRF MGMT that is used for this purpose; all 9 devices share a common management LAN and IPv4/v6 subnet. The goal is to sufficiently secure the routers so they can only be managed by authorized hosts, on authorized interfaces, using authorized protocols. We will also secure the control-plane (routing, ARP, etc) to the best of our ability using CPP/LPTS. Note: Sometimes CPP is called control plane protection (CPPr), which is a more generic term that covers management plane protection also.

One of the simplest CPP / LPTS features is management plane protection (MPP). This is a way of specifying through which interfaces, and using which protocols, a router can be managed. Because every router in this lab has an OOBM interface in a separate VRF specifically for management, it would make sense to disallow management protocols on other interfaces. Before beginning, we can see that CSR5 is allowing telnet sessions from anywhere. We could secure this with VTY ACLs, but CPP is another option.

```
R7#telnet 10.5.7.5
Trying 10.5.7.5 ... Open
R5#
```

CSR5 can specify which interfaces allow telnet to be processed by the router for management purposes. In this case, only Gig1, the OOBM interface, should be used. The configuration for MPP on XE happens under the “host” subinterface. We can select from a list of protocols for each interface we list. After applying this configuration, CSR7 can no longer telnet to CSR5. The TCP SYN is not rejected, but simply discarded, as generating a TCP RST takes CPU cycles.

```
! CSR5
```

```
control-plane host
management-interface GigabitEthernet1 allow ssh tftp snmp telnet
```

```
R7#telnet 10.5.7.5
Trying 10.5.7.5 ...
% Connection timed out; remote host not responding
```

This does not affect transit traffic; telnet can still pass through the router, and CSR7 is able to access CSR6 as an example.

```
R7#telnet 10.6.8.6 /source-interface loopback0
Trying 10.6.8.6 ... Open
R6#
```

Let's assume that CSR7 should be allowed to SSH into CSR6, but only Gig1 should support all protocols supported by the router. Though the parser says BEEP and TLS1 are options, IOS-XE notifies us that they are not supported. The full configuration is also shown below; it also reveals that typing "allow" by itself is just a macro for manually enabling all available management services.

```
R6(config-cp-host)#management-interface GigabitEthernet1 allow
TLS1 is not a supported management protocol in IOSXE. It will be ignored as
if it is not configured.
BEEP is not a supported management protocol in IOSXE. It will be ignored as
if it is not configured.
```

```
! CSR6
control-plane host
management-interface GigabitEthernet1 allow ftp http https ssh tftp snmp
beep telnet t11
management-interface GigabitEthernet2.568 allow ssh
```

External routers can SSH into CSR6 via Gig2.568 (as the target IP), but can no longer telnet. CSR9, the authorized management station, can do both.

```
R7#telnet 10.6.8.6 /source-interface lo0
Trying 10.6.8.6 ...
% Connection timed out; remote host not responding
```

```
R8#ssh -l test 10.6.8.6
Password:
```

```
R9#telnet 10.31.5.206
Trying 10.31.5.206 ... Open
R6#
```

```
R9#ssh -l test 10.31.5.206
Password:
```

This functionality can be verified using a single show command. Outputs from both CSR5 and CSR6 are shown below. It includes packet counters also.

```
R5#show management-interface
Management interface GigabitEthernet1
      Protocol      Packets processed
      ssh           0
      tftp           0
      snmp           0
      telnet        70
```

```
R6#show management-interface
Management interface GigabitEthernet1
      Protocol      Packets processed
      ftp           0
      http          0
      https         0
      ssh           30
      tftp          0
      snmp          0
      beep          0
      telnet        22
      t11           0
```

```
Management interface GigabitEthernet2.568
      Protocol      Packets processed
      ssh           30
```

The policing aspect of CPP is also powerful. This is commonly used to prevent common DoS attacks like ARP or ping flooding. My personal favorite outbound functionality is to police the rate at which ICMP unreachables are sent. Both XE and XR have one-line commands for this, but filtering the type of ICMP unreachable is valuable to achieve greater granularity in high-security networks. This example shows portions of a configuration that is used to protect CSR5 from ICMP unreachable CPU-hogging. Rather than disable ICMP unreachables on the transit interfaces, we allow the unreachables needed for PMTUd (packet-too-big), along with the familiar traceroute unreachables (port unreachable and time exceeded). This allows MPLS administrators to traceroute internally for troubleshooting, but ensures the routers don't give away "too" much information. It also allows customers to traceroute across the MPLS network to check their own connectivity within their VPN. The flexibility of MQC is beneficial because needing to enable/disable a new unreachable means modifying an ACL, which is straightforward. The syntax is nearly identical for IPv4 and IPv6, making it easy to read, operate, and troubleshoot. This is also an effective security mechanism when tied in with disabling MPLS TTL propagation (added on all four core routers but not shown).

```
! CSR5
ip access-list extended ACL_ALLOWED_ICMP_UNREACHABLES
```

```

    permit icmp any any time-exceeded
    permit icmp any any port-unreachable
    permit icmp any any packet-too-big
ip access-list extended ACL_DENIED_ICMP_UNREACHABLES
    permit icmp any any unreachable

ipv6 access-list ACL_ALLOWED_ICMPV6_UNREACHABLES
    permit icmp any any time-exceeded
    permit icmp any any port-unreachable
    permit icmp any any packet-too-big
ipv6 access-list ACL_DENIED_ICMPV6_UNREACHABLES
    permit icmp any any unreachable

class-map match-any CMAP_ALLOWED_ICMP_UNREACHABLES
    match access-group name ACL_ALLOWED_ICMP_UNREACHABLES
    match access-group name ACL_ALLOWED_ICMPV6_UNREACHABLES

class-map match-any CMAP_DENIED_ICMP_UNREACHABLES
    match access-group name ACL_DENIED_ICMP_UNREACHABLES
    match access-group name ACL_DENIED_ICMPV6_UNREACHABLES

policy-map PMAP_CPP_OUT
    class CMAP_ALLOWED_ICMP_UNREACHABLES
        police rate 10 pps burst 10 packets
        conform-action transmit
        exceed-action drop
    class CMAP_DENIED_ICMP_UNREACHABLES
        police rate 1 pps conform-action drop

```

The above configuration polices the allowed unreachable described earlier to 10 packets per second with no inter-packet limit until the limit of 10 is reached. Because IOS-XE does not have the “drop” keyword like IOS does, we can police the prohibited unreachable to any rate and set the conform action to drop. This means that, regardless of the generation rate, 100% of packets matching this class are dropped. We can further extend this policy to do some basic QoS marking for our outbound management traffic. In networks with only in-band management mechanisms, sometimes it isn’t always known from which interface a device will be managed. Using CPP (or local PBR) can obviate the need to make per-interface policies and risk double-classifying transit traffic. Anytime the router generates a “management” packet like syslog, TFTP, RADIUS, or FTP, it will be marked DSCP CS2 (DSCP 16).

```

! CSR5
ip access-list extended ACL_LOCAL_MGMT_TRAFFIC
    permit udp any any eq syslog
    permit udp any eq syslog any
    permit udp any any range 1812 1813
    permit udp any range 1812 1813 any
    permit udp any any eq tftp
    permit udp any eq tftp any

```

```

permit tcp any any range ftp-data ftp
permit tcp any range ftp-data ftp any

class-map match-all CMAP_LOCAL_MGMT_TRAFFIC
match access-group name ACL_LOCAL_MGMT_TRAFFIC

policy-map PMAP_CPP_OUT
class CMAP_LOCAL_MGMT_TRAFFIC
set dscp cs2

```

The policy now contains the ICMP unreachable limiting and QoS marking features. It is applied under the control-plane stanza and can be verified similar to a normal policy-map. Packets not classified by this policy are ignored (untreated).

```

! CSR5
control-plane
service-policy output PMAP_CPP_OUT

```

```

R5#show policy-map control-plane output | include Class|packet
Class-map: CMAP_ALLOWED_ICMP_UNREACHABLES (match-any)
  0 packets, 0 bytes
    rate 10 pps, burst 10 packets

Class-map: CMAP_LOCAL_MGMT_TRAFFIC (match-all)
  0 packets, 0 bytes
Class-map: class-default (match-any)
  16 packets, 6823 bytes

```

We will perform several tests to ensure the router takes actions in accordance with the CPP policies. First, we will traceroute to CSR5 from XRv1. CSR5 should originate “port unreachable” messages for each probe sent by XRv1. Since three probes were sent, three unreachables were generated.

```

RP/0/0/CPU0:XRv1#traceroute 23.0.0.5
Type escape sequence to abort.
Tracing the route to 23.0.0.5

```

```

1  23.5.11.5 0 msec 0 msec 0 msec

```

```

R5#show policy-map control-plane output | include Class|packet
Class-map: CMAP_ALLOWED_ICMP_UNREACHABLES (match-any)

    conformed 0 packets, 0 bytes; actions:
    exceeded 0 packets, 0 bytes; actions:
Class-map: CMAP_LOCAL_MGMT_TRAFFIC (match-all)
  0 packets, 0 bytes
Class-map: class-default (match-any)
  150 packets, 57709 bytes

```

Traceroute across CSR5, even from within a VRF, is subject to the same checks. This time, CSR5 originates the “time-exceeded” unreachable for CSR7 since XRv4 is farther away. XRv4 will generate the port unreachables, but that is regular transit traffic to the core routers.

```

R7#traceroute 10.14.14.14 source loopback0
Type escape sequence to abort.
Tracing the route to 10.14.14.14

Class-map: CMAP_LOCAL_MGMT_TRAFFIC (match-all)
  0 packets, 0 bytes
Class-map: class-default (match-any)
  276 packets, 106709 bytes

```

A static default route on CSR7 allows it to send bogus traffic to CSR5. We expect CSR5 to not originate any “host unreachable” or “network unreachable” messages, and expect to see five denials in the CPP counters. The catch-all of denying all other ICMP unreachables also includes these; this makes the policy simple by not having to enumerate every denied unreachable in “blacklist” form. Though these 5 packets conformed to the policer’s CIR, the conform-action is drop.

```

R7(config)#ip route 0.0.0.0 0.0.0.0 10.5.7.5

```

```
R7#ping 1.2.3.4
Type escape sequence to abort.
Sending 5, 100-byte ICMP Echos to 1.2.3.4, timeout is 2 seconds:
.....
Success rate is 0 percent (0/5)
```

```
R5#show policy-map control-plane output | include Class|packet
  Class-map: CMAP_ALLOWED_ICMP_UNREACHABLES (match-any)
    6 packets, 336 bytes
      rate 10 pps, burst 10 packets
      conformed 6 packets, 336 bytes; actions:
      exceeded 0 packets, 0 bytes; actions:
  Class-map: CMAP_DENIED_ICMP_UNREACHABLES (match-any)
    5 packets, 280 bytes
      rate 1 pps, burst 1 packets
      conformed 5 packets, 280 bytes; actions:
      exceeded 0 packets, 0 bytes; actions:
  Class-map: CMAP_LOCAL_MGMT_TRAFFIC (match-all)
    0 packets, 0 bytes
  Class-map: class-default (match-any)
    529 packets, 205423 bytes
```

Next, we will configure remote logging on CSR5 to send logs to CSR6 as a bogus syslog server. These packets should be marked DSCP CS2 by the router regardless of which interface or VRF they exit. CSR6 will use EPC to monitor these packets inbound. The TOS is 0x40 (0100 0000, decimal 64, or DSCP CS2) as shown by the packet dump. You can clearly see the log message inside the payload of the packet shown in green. I did this twice for sanity, which is why two packets are counted in the CPP policy. The policy could also include an IPv6 ACL to include IPv6 management ports, but I intentionally left that out to demonstrate that you can be selective.

```
! CSR5
logging host 23.0.0.6
```

```
R5#show policy-map control-plane output | include Class|packet
  Class-map: CMAP_ALLOWED_ICMP_UNREACHABLES (match-any)
    6 packets, 336 bytes
      rate 10 pps, burst 10 packets
      conformed 6 packets, 336 bytes; actions:
      exceeded 0 packets, 0 bytes; actions:
  Class-map: CMAP_DENIED_ICMP_UNREACHABLES (match-any)
    5 packets, 280 bytes
      rate 1 pps, burst 1 packets
      conformed 5 packets, 280 bytes; actions:
      exceeded 0 packets, 0 bytes; actions:
  Class-map: CMAP_LOCAL_MGMT_TRAFFIC (match-all)
    2 packets, 222 bytes
  Class-map: class-default (match-any)
```

992 packets, 387000 bytes

R6#show monitor capture CAP buffer dump

    214 packets, 82735 bytes

```

One final test on CSR5 is to test the policer for the unreachable. CSR6 will send 15 of traceroute probes and expect to see the 11th one dropped (green). CSR5 responds with 10 responses (yellow), drops one, and responds with the remaining 4. No other classes were matched, as expected. The total is now 18 packets; 3 from earlier plus 15 just now, and of those 15, 1 was in excess of the 10 pps rate.

```

```

We can also use CPP for inbound policing. For example, CSR5 and CSR6 already know what protocols must be accepted inbound (BGP, LDP, etc), so we can manually configure a policy to only allow those. As we will see later, LPTS on XR does this automatically, but CPP on XE does not. A router can have both inbound and outbound policies concurrently, but we will configure the inbound policy on CSR6 for variety. Specifically, the goals will be to allow BGP sessions to 23.0.0.5 (source port 179 only, since the RR is using dynamic peer-groups). LDP discovery (UDP) will be allowed for anyone in the 23.0.0.0/12 subnet with LDP sessions (TCP) allowed for 23.0.0.0/24. The LDP flows are unlimited for now, but we want to have a placeholder in the policy to limit it later. BGP is limited to 64 kbps and also must be DSCP CS6. Additionally, critical non-IP flows, such as ARP and IS-IS, will be policed to an aggregate of 32 kbps. All other BGP and LDP should be denied, with remaining unknown traffic allowed to pass. If you make a comprehensive policy, it will take longer to program and validate, so we will limit it to a few protocols. A “drop by default” policy is always more effective but requires more careful planning.

```

control-plane
service-policy input CMAP_CPP_IN

```

Attempting to match any kind of NBAR protocols, even IS-IS, is not allowed. The only “match protocol” option that appears to be supported is ARP, so we will police that only. That is why IS-IS is removed from the configuration above despite the desire to specify it. I tried to use “cls_is” instead of “isis” but the CSR1000v does not support that for any application.

```

! With class-map "match protocol isis"

232 packets, 70701 bytes

```

First, we will “clear arp” several times in quick succession to see if we can trip the policer. Probably not, but at least we see matches on the class. On a router with hundreds of interfaces (or a lower CIR), this would be easier. Of greater importance is confirming that the CPP policy is matching the ARP traffic.

```
R6#show policy-map control-plane input class CMAP_CRITICAL_NON_IP | include
packet
    311 packets, 19120 bytes
    conformed 311 packets, 19120 bytes; actions:
    exceeded 0 packets, 0 bytes; actions:
```

Next, we will clear BGP and LDP to ensure they can re-establish successfully from a cold state. This is an important step to ensure your ACLs are configured correctly and are not working coincidentally due to current session formation. We should see several more BGP and LDP hits. We also verify that the BGP and LDP neighbors came up successfully.

```
R6#show policy-map control-plane input class CMAP_ALLOWED_BGP | include
packet
    31 packets, 3954 bytes
    conformed 31 packets, 3954 bytes; actions:
    exceeded 0 packets, 0 bytes; actions:
```

```
R6# show policy-map control-plane input class CMAP_ALLOWED_LDP | include

        conformed 2 packets, 160 bytes; actions:
        exceeded 0 packets, 0 bytes; actions:

```

The MPP functionality in XR, as a component of LPTS, has the additional capability to specify interfaces as in-band or out-of-band. OOB interfaces can never be used for transit, even if there is a valid routing path, while in-band interfaces can. Typically, the OOBM interface will allow more management protocols on the device, while in-band may allow none or very few. In the example below, the OOB interface allows all protocols provided they are sourced from within the specified subnets. The inband interface only specifies the link to XRv4 and allows telnet sessions sourced from XRv4's loopback only, arriving on that directly-connected interface.

```

! XRv11
control-plane
management-plane
inband
    interface GigabitEthernet0/0/0/0.541
        allow Telnet peer
        address ipv4 10.14.14.14

out-of-band
    interface MgmtEth0/0/CPU0/0
        allow all peer
        address ipv4 10.31.5.128/25
        address ipv6 FD00:10:31:5::209

```

Before testing MPP, we can verify that the LPTS tables are correct. Note that you must enable the management services in question (telnet, SNMP, SSH, etc) before you'll see an LPTS entry. If the service is disabled, LPTS has no reason to create a permissive exception for it. The TCP entries are shown first. Notice how the OOB interface allows telnet from the specified subnets, while the inband interface only allows it from XRv14's (CE) loopback. You can think of these entries like reflexive ACLs in a way.

```

RP/0/0/CPU0:XRv1#show lpts bindings l4-protocol 6 brief

Some quick data tests show that our policy works. XRv14 can telnet only when sourced from the loopback0 and routing over the directly-connected link (MPP in-band on XRv1). Unlike CPP, this LPTS feature does send TCP RSTs since it's more like a stateless firewall or access-list.

```
RP/0/0/CPU0:XRv4#telnet 10.11.14.11
```

```
Trying 10.11.14.11...
```

```
telnet: Unable to connect to remote host: Connection refused
```

```
telnet[65692]: %IP-telnet-6-CONNECT : Couldn't connect to remote host
10.11.14.11(Connection refused).
```

```
RP/0/0/CPU0:XRv4#telnet 10.11.14.11 source-interface loopback0
```

```
Trying 10.11.14.11...
```

```
Use specified source interface(Loopback0).
```

```
Use 10.14.14.14 as local address.
```

```
Connected to 10.11.14.11.
```

All routers on the OOB LAN can telnet to XRv1, including CSR9, using IPv4. All of them have IPv4 addresses in the 10.31.5.128/25 range. Using IPv6, however, only CSR9 can. LPTS can be very flexible in this way without having to define complex ACLs.

```
R9#telnet 10.31.5.211
```

```
Trying 10.31.5.211 ... Open
```

```
R7#telnet 10.31.5.211 /vrf MGMT
```

```
Trying 10.31.5.211 ... Open
```

```
R9#telnet FD00:10:31:5::211
Trying FD00:10:31:5::211 ... Open

R7#telnet FD00:10:31:5::211 /vrf MGMT
Trying FD00:10:31:5::211 ...
% Connection refused by remote host
```

Several other LPTS entries are created totally dynamically. Below are the LPTS entries on XRv1 for BGP and LDP. The BGP sessions are preconfigured and known, but the LDP ones are built based on the UDP link-discovery mechanism. We can see the BGP session to CSR5 (RR) and XRv4 in 2 separate VRFs. Notice there are 4 entries; one is specified including the source port of the TCP client, while the other is a generic “listener” in a traditional TCP server role. When a new client is configured, the corresponding “listener” entry is added to the LPTS table. In routers that actually have line-cards, these entries are policed individually; a generic listener is scrutinized more heavily than an established session, for example. The show commands to see the policed rates aren’t available in XRv.

```
RP/0/0/CPU0:XRv1#show lpts bindings l4-protocol 6 brief | include 179
0/0/CPU0    TCP    LR  IPV4  TCP    default  any          23.0.0.11,48860 23.0.0.5,179
0/0/CPU0    TCP    LR  IPV4  TCP    default  any          23.0.0.11,179 23.0.0.5
0/0/CPU0    TCP    LR  IPV4  TCP    C        any          10.11.14.11,179 10.11.14.14
0/0/CPU0    TCP    LR  IPV4  TCP    C        any          10.11.14.11,179 10.11.14.14,21987
```

LDP works similarly. There are established sessions to CSR5 and XRv12 in the global table which are shown with their fully-qualified TCP port lists. The third entry is odd; this was created only because XRv1 is the TCP server in this connection, whereas for CSR5 it was the client. With XRv2 as a TCP client, I believe that LPTS assumes that TCP client reserves the right to tear-down and reestablish the session using a new port, which would explain the more liberal entry. Again, in a hardware platform, this would be policed more heavily than the established sessions.

```
RP/0/0/CPU0:XRv1#show lpts bindings l4-protocol 6 brief | include 646
0/0/CPU0    TCP    LR  IPV4  TCP    default  any          23.0.0.11,15666 23.0.0.5,646
0/0/CPU0    TCP    LR  IPV4  TCP    default  any          23.0.0.11,646 23.0.0.12,41852
0/0/CPU0    TCP    LR  IPV4  TCP    default  any          any,646 23.0.0.12
```

There isn’t a keyword for revealing it, but configuring IS-IS automatically allows CLNS traffic to be accepted by the control-plane. Many of the specific filters aren’t in play, since CLNS routing isn’t used.

```
RP/0/0/CPU0:XRv1#show lpts bindings brief | include CLNS
0/0/CPU0    CLNS  LR  CLNS  -      default  Gi0/0/0/0.512 - -
0/0/CPU0    CLNS  LR  CLNS  -      default  Gi0/0/0/0.551 - -
```

As a best practice, it usually makes sense to police totally unknown BGP/LDP entries (the equivalent of BGP/LDP “any any”) to zero, effectively dropping the traffic. There are some corner cases where not applying this draconian policer could be valuable, such as dynamically established LDP targeted session

of BGP dynamic neighbors (not supported in XR yet), but they are generally rare. Again, this cannot be demonstrated here since XRv doesn't support the syntax.

Personally, I use the "show lpts bindings" command to verify most LPTS MPP configurations, but two other concepts are important. There is an iFIB, or internal FIB, that exists on an individual linecard. This determines how packets are to be punted, and where. Some things can be punted to the linecard CPU, such as ARP and BFD, which saves resources. Other traffic like IGP/BGP updates need to go to the Route-Switch Processors (RSPs, the main CPUs), which is beyond the linecard through the router fabric. Here is a trimmed-down output of some iFIB entries. Because there are no linecard CPUs, everything is "delivered" to the RSP. If BFD worked on XRv, we could test it in conjunction with LPTS, but it doesn't.

```
RP/0/0/CPU0:XRv1#show lpts ifib brief

[snip]
```

The pre-iFIB (piFIB) shows the entries before they are added to the iFIB. This is the first level of filtering that happens and the iFIB entries are populated next. This shows additional delivery options such as reassemble (all IPv4 fragments) or drop ICMP pings, timestamps, and mask requests. The iFIB will deliver traffic after the piFIB has performed dropping or reassembly as needed.

Additional Reading – Reference configurations "cpp-lpts"

42. Describe, implement, and troubleshoot logging and SNMP security

42.1 Logging

This feature is discussed/tested in detail in the security section. Logging enhances security by notifying network administrators of a problem in the network. Logging on ACL matches and other critical events allows administrators (and machines) to correlate events and identify security vulnerabilities.

42.2 SNMP security

This feature is discussed/tested in detail in the security section. In summary, there are three common versions of SNMP. SNMPv1 used community strings, much like SNMPv2c, and both provide very little security. SNMPv3 introduces authentication and encryption for SNMP traffic, along with usernames and groups. These groups are assigned specific views into the network and the SNMPv3 architecture allows for very granular control of permissions. ACLs can also be used to restrict access for both IPv4 and IPv6.

43. Describe, implement, and troubleshoot timing

PTP and SyncE are not supported on the CSR1000v or XRv at this time as confirmed by Cisco engineering. Only NTP is analyzed from a configuration and troubleshooting perspective. PTP and SyncE basic operation and architectures are described in text only. Below is a brief comparison between NTP and PTP. SyncE doesn't directly compare to these IP-based protocols and their distribution mechanisms.

Characteristic	NTP	PTP
Accuracy	1 ms – 10 ms	100 ns – 100 us
Server (master) type	Hardware or software	Hardware only
Sync method	Client pull from server	Server push to client
In-path adjustments	None	Yes, via transparent blocks
Cost	Inexpensive	Expensive
Monitoring metrics	Minimal	Many

43.1 Network Time Protocol (NTP)

NTP is the oldest network timing protocol and is used in many networks to synchronize time to millisecond accuracy using IPv4/v6 as transport. It uses UDP port 123 and comes in 5 versions:

1. Version 0: Introduced round-trip delay and offset calculations, 10-100 ms accuracy.
2. Version 1: Formalized client-server and peer-to-peer models
3. Version 2: Introduced authentication
4. Version 3: Introduced algorithms to select the “best” server when multiple clocks disagreed, along with broadcast mode. Introduced NTP control messages as well.
5. Version 4: Introduced more accurate clock and various other improvements. This is the current Cisco default and can achieve 1-10 ms accuracy, ten times better than the original versions. It is backwards compatible as far as NTPv2; some Internet time sources still use NTPv2.

NTP uses “strata” to measure the accuracy of a clock, with stratum 0 being the best (most accurate) and stratum 16 being unreachable. Each network hop away from stratum N is assumed to be stratum N + 1. Cisco routers can be made NTP masters, but this is not recommended unless there is a direct attachment to a stratum 0 clocking device (not a network connection). NTP can operate in many modes (symmetric active/passive, client-service, broadcast, multicast, etc) and supports both IPv4 and IPv6. The network diagram is shown below and shows an SP core providing L3VPN and L2VPN services to various customers.

The SP core will use a combination of client-server and symmetric-active modes. CSR3 and CSR8 are the NTP masters for the core, with CSR8 having a lower stratum and thus being preferred. CSR8 supports IPv4 only while CSR3 is dual stack. Because authentication is such a simple topic in NTP, it is included

during the initial configuration. Of note, **NTP servers authenticate to clients**, which seems backwards when compared to other protocols. The logic is that the clients must be certain that they are receiving the correct time; that is to say, they should not accept time from untrusted sources. The “ntp authenticate” command tells the router (only needed on clients or symmetric-active peers) to actually authenticate a server/peer. The key must be defined, trusted, and applied to a server/peer to be effective. The default stratum is 8, which is used by CSR3. CSR3 uses the “prefer” keyword, which is meaningless in this context, and is used as a “tie breaker” when there are multiple NTP servers/peers. All other things being equal, such as strata, time quality, and other measurements, the “prefer” option selects this server/peer over the others.

```
! CSR3
ntp authentication-key 203 md5 NTP_CORE
ntp authenticate
ntp trusted-key 203
ntp master
ntp peer 203.0.0.8 key 203 prefer source Loopback0

! CSR8
ntp logging
ntp authentication-key 203 md5 NTP_CORE
ntp authenticate
ntp trusted-key 203
ntp master 4
ntp peer 203.0.0.3 key 203 source Loopback0
```

It may take tens of minutes for the local router to synchronize its clock, even as a master. This makes NTP very time-consuming to test. CSR3 and CSR8 should both claim to be synchronized. Most of the information is extraneous (low-level details), so filtering based on the synchronization state is often sufficient. Both clocks have a local-host IP address of 127.127.1.1 which implies they are local masters.

```
R3#show ntp status
Clock is synchronized, stratum 8, reference is 127.127.1.1
nominal freq is 250.0000 Hz, actual freq is 250.0000 Hz, precision is 2**10
ntp uptime is 2181200 (1/100 of seconds), resolution is 4000
reference time is D9AC9B12.07AE1490 (03:29:22.030 UTC Wed Sep 23 2015)
clock offset is 0.0000 msec, root delay is 0.00 msec
root dispersion is 2.40 msec, peer dispersion is 1.20 msec
loopfilter state is 'CTRL' (Normal Controlled Loop), drift is 0.000000000 s/s
system poll interval is 16, last update was 15 sec ago.
```

```
R8#show ntp status | include sync
Clock is synchronized, stratum 4, reference is 127.127.1.1
```

For faster convergence, we can adjust the min and max poll timers. These are NTP “hello” interval boundaries that determine how frequently peers can be polled. The values are read in terms of 2^x where x is the input value. The default for min/max is 6/10, which yields a 64 second minpoll and 1024

second (17 minute) maxpoll. We can adjust these to be faster on both routers. Before the adjustment, we can confirm the default values. The minpoll must be less or equal to the maxpoll.

```
R8#show ntp associations detail | include stratum|minpoll
127.127.1.1 configured, ipv4, our_master, sane, valid, stratum 3
minpoll = 4, maxpoll = 4
203.0.0.3 configured, ipv4, authenticated, insane, invalid, stratum 8
minpoll = 6, maxpoll = 10
```

```
! CSR8
ntp peer 203.0.0.3 key 203 minpoll 4 maxpoll 5 source Loopback0
```

```
! CSR3
ntp peer 203.0.0.8 key 203 minpoll 4 maxpoll 5 source Loopback0
```

We can confirm the change using the same show command as above, and also use debugging to verify the packet exchange. We can see the packets are about ~18 seconds apart which is close to 16 (2^4).

```
R8#show ntp associations detail | include stratum|minpoll
127.127.1.1 configured, ipv4, our_master, sane, valid, stratum 3
minpoll = 4, maxpoll = 4
203.0.0.3 configured, ipv4, authenticated, insane, invalid, stratum 8
minpoll = 4, maxpoll = 5
```

```
! CSR8
03:40:47.202: NTP message sent to 203.0.0.3, from interface 'Loopback0'
(203.0.0.8).
03:40:52.032: NTP message received from 203.0.0.3 on interface 'Loopback0'

(203.0.0.8).
03:41:23.203: NTP message sent to 203.0.0.3, from interface 'Loopback0'
(203.0.0.8).
03:41:25.032: NTP message received from 203.0.0.3 on interface 'Loopback0'
(203.0.0.8).
```

Looking more closely at the association details, the two servers successfully authenticate one another but fail to acknowledge the accuracy of one another's clock. Unfortunately, the debugs do not appear to offer any valuable information as the configuration appears correct. The insane/invalid message is typically shown when the offset is less than -1000 ms or greater than +1000 ms (so +/- 1 second). Clearly our offset is within the bounds at -2 ms, yet the two cannot synchronize. Looking at the detailed output below, we confirm the small offset and successful authentication. The "reach" variable is an octal representation of the last 8 packets received. The number is in octal, so 377 is 11111111 in binary. This means that all of the last 8 packets were successfully received (right to left). A value of 367 is 11110111

would indicate that the fourth newest packet was dropped, for example. We also see the poll intervals at 2^4 (16) for both the remote and local NTP speakers. The mode is symmetric-active since both routers have a “peer” statement for one another.

```
R3#show ntp associations detail
203.0.0.8 configured, ipv4, authenticated, insane, invalid, stratum 4

```

The output is very similar on CSR8, showing no indication of failure with the offset, authentication, packet loss, or poll interval. The peers remain unsynchronized, though. This is likely related to two different masters trying to synchronize with slightly different times.

```

```

We can test symmetric passive mode instead, which involves configuring the peer on only one side (passive router must be the lower stratum router, CSR8). We can see the peer is now dynamic from CSR3’s perspective and the local mode is passive. “Reach” indicates the past 3 packets were received, but the first 5 were not (00000111); technically since this is a new peer, only 3 packets have been exchanged, and this number will approach 377 over time. The symmetric mode feature, both active and passive, appears to be broken in this version of the CSR1000v between two masters.

```

The remaining 4 SP routers will reference both NTP servers using IPv4 for CSR8 and IPv6 for CSR3. The XR configuration is very similar to XE except it goes into an NTP stanza. The update-calendar command is also available on IOS/XE hardware routers which tells NTP to update the hardware clock based on the software clock. Even though XRv clearly doesn't have a hardware clock, it still has a concept of a one, along with the appropriate command syntax. CSR does not.

```

```

More oddities from NTP are present when we verify CSR7 for synchronization. It has access to a stratum 4 and stratum 8 clock, yet it synchronizes to the worse stratum clock. It also displays a bogus IPv4 address which must be some representation of ::203:0:0:3, the IPv6 address of the current master. Clearly CSR8 has a been stratum but was not selected. The offsets are very close and no received packets were lost. It appears that having multiple, unsynchronized NTP masters in the network concurrently breaks many things.

```
R7#show ntp status | include sync
```

```
Clock is synchronized, stratum 9, reference is 177.221.165.15
```

```
R7#show ntp associations
```

address	ref clock	st	when	poll	reach	delay	offset	disp
+~203.0.0.8	127.127.1.1	4	10	32	377	2.000	-1.000	2.150
*~::203:0:0:3	127.127.1.1	8	4	32	377	4.000	0.000	2.117

* sys.peer, # selected, + candidate, - outlyer, x falseticker, ~ configured

Digging deeper, CSR7 seems to claim that CSR8 has association packet errors, and this might be the reason why it cannot be synchronized. Unlike CSR3, CSR7 actually considers CSR8 as sane/valid, which generally means it should be the master given the lower stratum. The debug does not seem to indicate anything extraordinary, either. It might be specific to NTP with IPv4 since the IPv6 features appear to work more reliably.

```
R7#show ntp associations detail | include stratum|assoc

```

Verifying the XRv is simple and appears to be working. CSR8 is correctly selected as the NTP master given the lower stratum of 4 (versus CSR3's stratum of 8). The outputs are almost identical to XE. We can clearly see that CSR8 is the current master, so there is no need to troubleshoot these associations. This reinforces the possibility of an issue with IPv4 NTP on XE routers.

```
RP/0/0/CPU0:XRv1#show ntp status | include sync
```

```
Clock is synchronized, stratum 5, reference is 203.0.0.8
```

```
RP/0/0/CPU0:XRv1#show ntp associations
```

address	ref clock	st	when	poll	reach	delay	offset	disp
+~::203:0:0:3	127.127.1.1	8	28	32	377	0.98	4.628	2.416
*~203.0.0.8	127.127.1.1	4	21	32	377	0.98	1.157	2.427

We can add additional security to NTP by applying access-lists. The lists are processed in the following order, from least restrictive to most restrictive:

1. Peer: Identifies NTP speakers who are allowed to update your clock
2. Serve: Identifies NTP speakers who can be updated by you, and can issue control queries
3. Serve-only: Identifies NTP speakers who can be updated by you, but cannot query
4. Query-only: Identifies NTP speakers who can query you, but not receive time

A deny entry placed in any ACL will automatically deny that level of privilege and everything beneath it. For example, an explicit “deny any” at the end of a “peer” ACL will deny all NTP to service to any NTP speaker not permitted in the peer ACL. The other three categories would also be denied as the ACLs are processed in the sequence outlined above. This feature is best illustrated with some examples. We will first secure our NTP masters, CSR3 and CSR8. CSR8 only has to worry about IPv4; the peer list specifies that only CSR3 is allowed to update CSR8’s clock. The serve list specifies that anyone with address 203.0.0.0 – 203.0.0.15 (loopbacks in the core) can receive time and query the master. CSR3’s ACLs follow the same logic but includes IPv6 also. Because no IPv6 peer list has been defined, no IPv6 NTP speaker is allowed to update CSR3’s clock, which makes sense since the only symmetric peer is IPv4-only (CSR8).

```
! CSR8
ip access-list standard ACL_NTP_PEER
  permit 203.0.0.3

ip access-list standard ACL_NTP_SERVE
  permit 203.0.0.0 0.0.0.15

ntp access-group peer ACL_NTP_PEER
ntp access-group serve ACL_NTP_SERVE

! CSR3
ip access-list standard ACL_NTP_PEER
  permit 203.0.0.8

ip access-list standard ACL_NTP_SERVE
  permit 203.0.0.0 0.0.0.15

ipv6 access-list ACL_NTP_SERVE_IPV6
  permit ipv6 ::203:0:0:0/120 host ::203:0:0:3

ntp access-group peer ACL_NTP_PEER
ntp access-group serve ACL_NTP_SERVE
ntp access-group ipv6 serve ACL_NTP_SERVE_IPV6
```

There isn’t a good way to verify this configuration is working other than checking the ACL counters. On CSR3, we can see counters on all three lists. Currently, CSR3 has no IPv4 clients, but at one time it did, which is why there are 421 matches compared to the thousands of matches in other categories.

```
R3#show access-lists | section NTP
Standard IP access list ACL_NTP_PEER
  10 permit 203.0.0.8 (1653 matches)
Standard IP access list ACL_NTP_SERVE
  10 permit 203.0.0.0, wildcard bits 0.0.0.15 (421 matches)
IPv6 access list ACL_NTP_SERVE_IPV6
  permit ipv6 ::203:0:0:0/120 host ::203:0:0:3 (6609 matches) sequence 10
```

When a packet is denied, NTP logging can help reveal it for troubleshooting. To illustrate the case above, CSR3's IPv6 serve list is augmented with a "deny" statement for XRv1 as a client. While this won't affect communication to CSR8 or other clients, it breaks all XRv1's ability to receive time.

```
! CSR3
ipv6 access-list ACL_NTP_SERVE_IPV6
  deny ipv6 host ::203:0:0:11 host ::203:0:0:3
  permit ipv6 ::203:0:0:0/120 host ::203:0:0:3

R3#show access-list ACL_NTP_SERVE_IPV6
IPv6 access list ACL_NTP_SERVE_IPV6
  deny ipv6 host ::203:0:0:11 host ::203:0:0:3 (1 match) sequence 5
  permit ipv6 ::203:0:0:0/120 host ::203:0:0:3 (6763 matches) sequence 10

! CSR3
NTP Core (NOTICE): ntp_receive: dropping message: restricted..
```

We can also secure the clients using similar logic. Since the clients should never serve time to anyone, a "deny any" list can be used to ensure the serve, serve-only, and query-only functions are totally disabled. The only "peers" who can update the client clocks are CSR3 and CSR8. Since we have two functions (peer and serve) using two routed protocols (IPv4 and IPv6), we need 4 access-lists. **Pitfall: the NTP ACLs on XR can never process the destination addresses and these MUST be "any".** Specifying the loopback or any other local address causes the ACL entry to be unmatched, resulting in NTP synchronization failures. The XE IPv4 ACL is standard, so the issue is moot, but the XE IPv6 ACL does work with destination addresses as demonstrated below. Technically, there is no need for a serve list, since the implicit deny from the peer-ACL will ensure that the serve, serve-only, and query-function functionality is disabled. Having the explicit ACL can be useful for counting ACL entry hits, which is valuable for troubleshooting. The minimalist approach would only require two "peer" lists. The "log" option is also supported for NTP for additional detail, but is not included in this configuration.

```
! CSR7 and CSR9
ip access-list standard ACL_NTP_PEER
  permit 203.0.0.8

ip access-list standard ACL_NTP_SERVE
  deny any

ipv6 access-list ACL_NTP_PEER_IPV6
```

```

permit ipv6 host ::203:0:0:3 host ::203:0:0:7 ! (or :9 for CSR9)

ipv6 access-list ACL_NTP_SERVE_IPV6
deny ipv6 any any

ntp access-group peer ACL_NTP_PEER
ntp access-group serve ACL_NTP_SERVE
ntp access-group ipv6 peer ACL_NTP_PEER_IPV6
ntp access-group ipv6 serve ACL_NTP_SERVE_IPV6

! XRv1 and XRv2
ipv4 access-list ACL_NTP_PEER
10 permit ipv4 host 203.0.0.8 any

ipv4 access-list ACL_NTP_SERVE
10 deny ipv4 any any

ipv6 access-list ACL_NTP_PEER_IPV6
10 permit ipv6 host ::203:0:0:3 any

ipv6 access-list ACL_NTP_SERVE_IPV6
10 deny ipv6 any any

ntp
access-group ipv4 peer ACL_NTP_PEER
access-group ipv4 serve ACL_NTP_SERVE
access-group ipv6 peer ACL_NTP_PEER_IPV6
access-group ipv6 serve ACL_NTP_SERVE_IPV6

```

We can confirm packet counters for the permit statements with none for the deny statements, indicating a proper configuration. These clients are not allow to serve time or control messages to anyone, but can be updated from the two NTP masters as specified in the ACL.

```

R9#show access-lists
Standard IP access list ACL_NTP_PEER
 10 permit 203.0.0.8 (2588 matches)
Standard IP access list ACL_NTP_SERVE
 10 deny any
IPv6 access list ACL_NTP_PEER_IPV6
 permit ipv6 host ::203:0:0:3 host ::203:0:0:9 (2588 matches) sequence 10
IPv6 access list ACL_NTP_SERVE_IPV6
 deny ipv6 any any sequence 10

RP/0/0/CPU0:XRv2#show access-list ipv4
ipv4 access-list ACL_NTP_PEER
 10 permit ipv4 host 203.0.0.8 any (11 matches)
ipv4 access-list ACL_NTP_SERVE
 10 deny ipv4 any any

```

```
RP/0/0/CPU0:XRv2#show access-list ipv6
ipv6 access-list ACL_NTP_PEER_IPV6
 10 permit ipv6 host ::203:0:0:3 any (10 matches)
ipv6 access-list ACL_NTP_SERVE_IPV6
 10 deny ipv6 any any
```

NTP has many other minor features associated with it. One of them is the concept of an “orphan”. An NTP orphan scenario occurs when all NTP servers are unreachable. Ideally, synchronizing to UTC time is desirable, but when this is impossible, synchronizing to something common between nodes in an NTP “mesh” is the next best thing. Cisco recommends enabling this command on all servers and clients, and ensuring clients can reach all of the orphan servers. XR does not appear to support this feature, so we will enable it on the XE core routers. Cisco also recommends taking the maximum stratum in the network and adding 2 to it, which yields 11 in our case. The orphan server will not be enabled until the current stratum is worse than the orphan value (if sync is lost, the stratum will be 16, which is always worse than the orphan value).

```
! CSR3, CSR7, CSR8, CSR9
ntp orphan 11
```

We can test this by temporarily disabling “ntp master” on CSR3 and CSR8 (not shown). The clocks on these routers remain synchronized, but do so at stratum 11 and use a new reference, 127.0.0.1.

```
R8#show ntp status | include sync
Clock is synchronized, stratum 11, reference is 127.0.0.1
```

Interestingly, we see that orphan mode appears to work well between CSR3 and CSR8, likely because there isn’t a competing set of master clocks. CSR3 synchronizes to CSR8 as the orphan master, and symmetric passive mode is still in effect. Notice that the stratum is 12 on CSR3, which is one number greater than the orphan stratum identified on CSR8.

```
R3#show ntp status | include sync
Clock is synchronized, stratum 12, reference is 203.0.0.8
```

```
R3#show ntp associations detail | include stratum|our_mode
203.0.0.8 dynamic, ipv4, authenticated, our_master, sane, valid, stratum 11
our mode passive, peer mode active, our poll intvl 64, peer poll intvl 32
```

CSR9, as a client, has similar output. Because the clocks are still skewing, CSR9 thinks that CSR8 has the wrong time and selects CSR3, despite the clocks being about the same. Regardless, we can see that orphan mode is “working”. Routers autonomously select orphan servers, so I suppose it is possible that CSR9 selected CSR3 over CSR8 coincidentally. The details of this selection aren’t very clear (or relevant).

```
R9#show ntp associations detail | include stratum|our_mode
```

```
203.0.0.8 configured, ipv4, authenticated, insane, invalid, stratum 11
our mode client, peer mode server, our poll intvl 32, peer poll intvl 32
```

```
::203:0:0:3 configured, ipv6, authenticated, our_master, sane, valid, stratum
12
our mode client, peer mode server, our poll intvl 32, peer poll intvl 32
```

Another minor option is the NTP panic update. This alerts the user when the configured and received times are more than 1000 seconds (~16 minutes) apart.

```
! CSR7, CSR9
ntp panic update
```

We set CSR3's clock to be a totally wrong time; CSR9 shows a log message saying that the peer's clock is "way too off". The values in the first message are 0 but I believe this is a cosmetic choice as Cisco states it should show the actual values. Oddly, CSR9 still synchronizes to CSR3, and I assume this will change over time. It calls CSR8 insane/invalid despite a .5 ms offset, and calls CSR3 sane/valid despite thousands of seconds of offset.

```
R3#clock set 00:00:00 26 sep 2015
```

```
! CSR9
NTP Core (INFO): ::203:0:0:3 F68A 8A sys_peer
NTP Core (ERROR): Time correction of 0. seconds exceeds sanity limit of 0.
seconds.
Set clock manually to the correct UTC time.
NTP Core (ERROR): Peer's clock is way too off. Local clock not updated
```

```
R9#show ntp associations detail | include stratum|offset

```

Before continuing, we enable NTP master on CSR3/CSR8 again to disable orphan mode. More options include the burst and iburst features that can be applied to an NTP server or peer and allow NTP to synchronize faster. These are enabled by default in newer code releases. Burst will send 8 packets, as opposed to 2, to a peer that is newly reachable. This is done to converge in a few minutes rather than tens of minutes. The other option, iburst, performs identically except does so for the "initial" burst. This happens when a peer becomes unreachable and, as a client, we want to discover it. Both are considered inappropriate when communicating to Internet NTP servers as it can appear like an attack, yet I am not sure how to disable it in Cisco IOS. The "normal-sync" option only applies to symmetric-mode (peer) and doesn't even show up in the configuration when applied. We won't evaluate this any further.

```
R8(config)#ntp server 1.1.1.1 ?
burst      Send a burst when peer is reachable (Default)
iburst     Send a burst when peer is unreachable (Default)
```

We can also specify the maximum and minimum distance that adjust how synchronization occurs. “Maxdistance” is misleading; with an input range of 1 – 16, one would assume this is the “worst possible stratum” value so that NTP peers don’t accidentally synchronize with terrible clocks. The command does something entirely different; it sets the number of packets required for synchronization. The default used to be 1, but is now 8. Increasing this value means that more packets are required for synchronization to occur. This increases network load but potentially increases reliability. We will use a more liberal value of 4 so that synchronization occurs faster but potentially less accurately.

```
! CSR7 and CSR9
ntp maxdistance 4
```

Mindistance, however, is not well documented and is configured in the range from 1 – 500 with unspecified units. We won’t configure it; non-Cisco documentation indicates that it is the sum of the offset and jitter, measured in seconds, but the command is absent from the XE 3S command reference.

```
R7(config)#ntp mindistance ?
<1-500>    Minimum distance to consider for clockhop
```

Another interesting command is the “passive” option. Cisco documentation suggests that it is used to accept passive associations. No explicit mention is made about symmetric-passive, and since CSR3 is a symmetric passive peer of CSR8 (for IPv6) and did not require this command, I am unsure of its purpose. The context-sensitive help does not provide any assistance either. It is not configured anywhere and is shown below for reference.

```
R3(config)#ntp ?
passive          NTP passive mode
```

NTP can also limit to number of associations. This is valuable in many scenarios. For CSR7 and CSR9, they should have exactly two associations, none of which are dynamic, so using max = 2 would protect them from learning a dynamic peer. For peers that only have dynamic associations (symmetric passive, broadcast, multicast), setting an upper-bound can conserve router resources, ultimately increasing security. The command is also supported on XR, so we configure it on XRv1 and XRv2.

```
! CSR7 and CSR9
ntp max-associations 2
```

```
! XRv1 and XRv2
ntp
max-associations 2
```

After completing all of the NTP configuration within the core, we can quickly verify that all of the routers still have time synchronization before continuing. We can also check the packet statistics to make sure our security mechanisms did not cause any errors. We will check the NTP masters for packet statistics as they have the most NTP traffic; we see no errors. **Pitfall: After a reboot, XRv NTP appears to never synchronize despite the clock skewing towards accurate time. You must delete all NTP configuration (no ntp), then reapply. It will synchronize almost immediately.**

```
R3#show ntp status | include sync
Clock is synchronized, stratum 8, reference is 127.127.1.1
```

```
R7#show ntp status | include sync
Clock is synchronized, stratum 5, reference is 203.0.0.8
```

```
R8#show ntp status | include sync
Clock is synchronized, stratum 4, reference is 127.127.1.1
```

```
R9#show ntp status | include sync
Clock is synchronized, stratum 5, reference is 203.0.0.8
```

```
RP/0/0/CPU0:XRv1#show ntp status | include sync
Clock is synchronized, stratum 5, reference is 203.0.0.8
```

```
RP/0/0/CPU0:XRv2#show ntp status | include sync
Clock is synchronized, stratum 5, reference is 203.0.0.8
```

```
R3#show ntp packets
Ntp In packets           : 25584
Ntp Out packets          : 25584
Ntp bad version packets  : 0
Ntp protocol error packets : 0
```

```
R8#show ntp packets
Ntp In packets           : 25581
Ntp Out packets          : 25588
Ntp bad version packets  : 0
Ntp protocol error packets : 0
```

Next, we will examine NTP multicast delivery. CSR1 is the NTP server for the customer L3VPN and is serving time to CSR5, CSR6, CSR10, and XRv3. CSR1 has both an IPv4 and IPv6 multicast NTP service available. The global NTP configuration is nothing new. We must configure NTP as a multicast sender on the PE-CE link so that XRv2 can register the source with the C-RP. We configure both an IPv4 and IPv6 multicast stream and re-use authentication keys for simplicity.

```
! CSR1
ntp logging
ntp authentication-key 65000 md5 NTP_MCAST
```

```

ntp trusted-key 65000
ntp master

interface GigabitEthernet2.512
 ntp multicast FF08::1:2:3 key 65000
 ntp multicast 225.1.2.3 key 65000

```

We also must configure receivers. Since NTP is using an IGMP membership report behind the scenes, we must enable PIM on the NTP client interface. It also makes sense to configure this on loopbacks for routers that have multiple transit links like CSR10 and XRv3. CSR5 is the only router requesting IPv4-only timing service.

```

! All three CSR clients
ip multicast-routing distributed

ntp logging
ntp authentication-key 65000 md5 NTP_MCAST
ntp authenticate
ntp trusted-key 65000

! CSR5
interface GigabitEthernet2.556
 ip pim sparse-mode
 ntp multicast client 225.1.2.3

! CSR6 and CSR10
ipv6 multicast-routing

interface Loopback0
 ip pim sparse-mode
 ntp multicast client 225.1.2.3
 ntp multicast client FF08::1:2:3

! XRv3
multicast-routing
 address-family ipv4
  interface all enable

 address-family ipv6
  interface all enable

ntp
 interface Loopback0
  multicast client 225.1.2.3
 authentication-key 65000 md5 NTP_MCAST
 authenticate
 trusted-key 65000
 update-calendar

```

```
log-internal-sync
```

We can see that CSR6 sees membership reports from CSR5 and CSR6 (itself). Note that NTP normally uses group 224.0.1.1 but I demonstrate a new group for variety. CSR6 has the correct (*,G) entry with the RP as XRv3 (configuration not shown) with both the local loopback and CSR5 in the OIL. The (S,G) entry, once CSR1 starts sending, is also accounted for.

```
R6#show ip igmp groups 225.1.2.3
IGMP Connected Group Membership
Group Address      Interface                Uptime    Expires    Last Reporter
Group Accounted
225.1.2.3          GigabitEthernet2.556    20:08:57  00:02:32   10.5.6.5
225.1.2.3          Loopback0                20:09:11  00:02:53   10.6.6.6
```

```
R6#show ip mroute 225.1.2.3 | begin \
(*, 225.1.2.3), 20:11:01/stopped, RP 10.13.13.13, flags: SJCL
Incoming interface: GigabitEthernet2.561, RPF nbr 10.6.11.11
Outgoing interface list:
Loopback0, Forward/Sparse, 20:10:59/00:02:01
GigabitEthernet2.556, Forward/Sparse, 20:10:46/00:02:44

(10.1.12.1, 225.1.2.3), 19:51:09/00:02:09, flags: LJT
Incoming interface: GigabitEthernet2.561, RPF nbr 10.6.11.11
Outgoing interface list:
GigabitEthernet2.556, Forward/Sparse, 19:51:09/00:02:44
Loopback0, Forward/Sparse, 19:51:09/00:02:01
```

We can check the flow of traffic by checking the packet counts against the (S,G) entry.

```
R6#show ip mroute 225.1.2.3 10.1.12.1 count | begin ^Group
Group: 225.1.2.3, Source count: 1, Packets forwarded: 1090, Packets received:
1090
Source: 10.1.12.1/32, Forwarding: 1089/0/114/0, Other: 1089/0/0
```

Checking CSR5, we can see that NTP is receiving packets and is synchronized to CSR1.

```
R5#show ntp packets
Ntp In packets          : 1104
Ntp Out packets         : 10
Ntp bad version packets : 0
Ntp protocol error packets : 0
```

```
R5#show ntp status | include sync
Clock is synchronized, stratum 9, reference is 10.1.12.1
```

Note that CSR6 does not sync to the IPv4 address but rather uses the IPv6 address. Debugging reveals that CSR6 doesn't think it is an IPv4 NTP client when it clearly is. **It does not appear supported to use IPv4 multicast on a loopback for NTP client (check the release notes for your version).** This works fine on XRV and IPv6 works fine on both platforms. Notice that the debug also shows a successfully processed IPv6 multicast packet. We already saw that CSR6 was locally joining the IPv4 multicast group, so we also prove that it is locally joining the IPv6 group as well.

```
R6#show ipv6 mld groups ff08::1:2:3
MLD Connected Group Membership
Group Address                Interface      Uptime    Expires
FF08::1:2:3                  Loopback0     00:52:06  never
```

```
R6#debug ntp packet
NTP IPv4 multicast message discarded: not an NTP multicast client for
225.1.2.3
NTP message received from FD00:10:1:12::1 on interface 'Loopback0',
(FF08::1:2:3), table 0.
```

```
NTP Core(DEBUG): ntp_receive: message received
NTP Core(DEBUG): ntp_receive: peer is 0x00000000, next action is 6.
NTP IPv6 message sent to FD00:10:1:12::1, from FE80::21E:BDFF:FE69:6200,
table = 0, interface Loopback0.
```

```
R6#show ntp status | include sync
Clock is synchronized, stratum 9, reference is 65.190.62.223
```

After awhile, CSR6 will eventually show that the IPv6 peer is reachable and the clock will synchronize as shown above. Also note that the local mode is "xcast client", which I assume means multicast OR broadcast client. The peer FD00:10:1:12::1 is the NTP server, as expected. The detailed output also shows the correct (not weird IPv4-ish) IPv6 address of the dynamically-discovered NTP server.

```
! CSR6
NTP Core (INFO): FD00:10:1:12::1 6024 84 reachable
NTP Core (INFO): 0.0.0.0 C02C 0C clock_step
NTP Core (INFO): FD00:10:1:12::1 763A 8A sys_peer
NTP Core (NOTICE): Clock is synchronized.
```

```
R6#show ntp associations detail | include stratum|our_mode
FD00:10:1:12::1 dynamic, ipv6, authenticated, our_master, sane, valid,
stratum 8
our mode xcast client, peer mode server, our poll intvl 64, peer poll intvl
64
```

Likewise, CSR10 has the same problem as CSR6 and will not accept IPv4 multicast on the loopback. Again, it shows the IPv6-translated version of the IPv4 address.

```
R10#show ntp status | include sync
Clock is synchronized, stratum 9, reference is 65.190.62.223
```

```
R10#show ntp packets
Ntp In packets : 277
Ntp Out packets : 3
Ntp bad version packets : 0
Ntp protocol error packets : 0
```

XRv3 is not an IPv6 client since it actually does work with IPv4 on the loopback. Below we can see the IPv4 NTP server used, along with the association details. I am not sure what “our mode control” means, but we know XRv3 is functioning as an NTP IPv4 multicast client.

```
RP/0/0/CPU0:XRv3#show ntp status | include sync
Clock is synchronized, stratum 9, reference is 10.1.12.1
```

```
RP/0/0/CPU0:XRv3#show ntp associations detail | utility egrep 'stratum|^our'
10.1.12.1 dynamic, authenticated, our_master, stratum 8
our mode control, peer mode bdcast, our poll intvl 1024, peer poll intvl 1024
```

Last, we will examine broadcast distribution using NTP. This is simpler than multicast because it cannot be routed but can touch all hosts on a LAN. It is also limited to a single broadcast domain, so we will use CSR4 as the master for the L2VPN customer. For extra security, we use different authentication keys for CSR2 and XRv4. We can also specify the directed broadcast address if we choose versus 255.255.255.255 which is the default. The client configuration is similar to multicast except there is no need to specify a group.

```
! CSR4
ntp logging
ntp authentication-key 24 md5 NTP_BCAST
ntp authentication-key 414 md5 NTP_L2VPN
ntp trusted-key 414
ntp trusted-key 24
ntp master

interface GigabitEthernet2.524
 ntp broadcast key 24 destination 10.2.4.255

interface GigabitEthernet2.549
 ntp broadcast key 414

! CSR2
ntp logging
ntp authentication-key 24 md5 NTP_BCAST
ntp authenticate
ntp trusted-key 24
```

```

interface GigabitEthernet2.524
 ntp broadcast client

! XRv4
ntp
 interface GigabitEthernet0/0/0/0.574
  broadcast client

 authentication-key 414 md5 NTP_L2VPN
 authenticate
 trusted-key 414
 log-internal-sync

```

Since CSR4 is sourcing these broadcasts from its LAN interfaces towards both peers, the NTP server IP address is different on each LAN, but they all reference CSR4.

```

R2#show ntp status | include sync
Clock is synchronized, stratum 9, reference is 10.2.4.4

RP/0/0/CPU0:XRv4#show ntp status | include sync
Clock is synchronized, stratum 9, reference is 10.4.14.4

```

The details indicate that the mode is “xcast client” where CSR4 is a server. Because this “xcast” string is shown for multicast and broadcast, I assume that the NTP underpinning don’t differentiate, and only higher layer protocols like IGMP, MLD, and PIM really make the difference. Like symmetric passive and multicast clients, the association was dynamic since “10.2.4.4” does not exist in CSR2’s configuration anywhere. The output is similar for XRv except that it says the local mode is “control”, which is a little confusing.

```

R2#show ntp associations detail | include stratum|our_mode
10.2.4.4 dynamic, ipv4, authenticated, our_master, sane, valid, stratum 8
our mode xcast client, peer mode xcast server, our poll intvl 64, peer poll
intvl 64

RP/0/0/CPU0:XRv4#show ntp associations detail | utility egrep 'stratum|^our'
10.4.14.4 dynamic, authenticated, our_master, stratum 8
our mode control, peer mode bdcast, our poll intvl 1024, peer poll intvl 1024

```

The CSR1000v also supports Simple NTP (SNTP). This is very similar to NTP from a network perspective; it supports unicast, multicast, and broadcast transport, uses UDP port 123, and can be authenticated. CSR1000v does not support SNTP ACLs or multicast/broadcast server, only client. SNTP uses simpler, less CPU intensive time algorithms (simple time stepping) and is meant to be used on lower-end platforms or small devices. SNTP is also a good fit for simple applications where accuracy and reliability are not terribly important. It is recommended to only be used at the extremities of the network and certainly not in the core of the NTP distribution tree. XR does not support this feature at all. Rather than

extensively test it, the available commands are shown below, and there is no support for interface level commands. SNTP and NTP are mutually exclusive on a router and cannot be configured concurrently.

```
R4(config)#sntp ?
authenticate      Authenticate time sources
authentication-key Authentication key for trusted time sources
broadcast         Configure SNTP broadcast services
logging           Enable SNTP message logging
multicast         Configure SNTP multicast services
server            Configure SNTP server
source-interface  Configure interface for source address
trusted-key       Key numbers for trusted time sources
```

Additional Reading – Reference configurations "ntp"

43.2 1588v2 (Precision Time Protocol(PTP))

Precision Time Protocol (PTP), also called IEEE 1588-2008 or IEEE 1588v2, is used to convey time and frequency information across an IP network. It was created because existing mechanisms, such as NTP and GPS, were insufficient for all needs. Putting a GPS receiver at every node is unaffordable and sometimes not physically possible, and NTP cannot achieve accuracy beyond milliseconds in many networks. PTP defines a master-slave relationship for timing distribution much like NTP. Clocks are identified as “ordinary” or “boundary”. Ordinary clocks are typically endpoints with a single network connection (host device) which can be a master or slave clock. A boundary clock has multiple network connections and synchronizes time across network segments (router). Both ordinary and boundary locks can be identified as master clocks. Boundary clocks are like NTP clocks that are nodes in a tree where masters are upstream and slaves are downstream. There is a concept of grandmaster as well, where the grandmaster is the root timing reference from which timing is derived. IEEE 1588-2008 introduced the concept of a transparent clock which modifies PTP messages transiting it to account for network latency time for packets in transit. This helps the downstream clocks to have more accurate timing; NTP has no mechanism for adjusting transit NTP packets.

PTP uses several different messages to synchronize time. Messages are categorized as “event” or “general” messages. Events are time-sensitive as the timestamps directly affect the timing of the PTP nodes (sync, delay, etc). General messages are important to PTP, but their time sensitivity is insignificant (announce, management, signaling, etc).

- a. **Sync, delay_req, follow up, delay_resp:** Core synchronization messages to communicate time related information between PTP clocks.
- b. **Announce:** Used by the best master clock (BMC) algorithm to select the best clock. It can build a clock hierarchy based on “quality” and select the grandmaster clock.
- c. **Management:** Used to monitor, configure, and maintain PTP clocks.
- d. **Signaling:** Used for non-time-critical communications between clocks.

The BMC algorithm takes many components into account.

- a. **Identifier:** Unique identifier for a clock. This is based on the MAC address of the device.
- b. **Quality:** This is based on expected timing deviation and other advanced math.
- c. **Priority:** Administratively assigned precedence to select a grandmaster, which is two 8-bit priority fields. The first priority is the big “hammer” which is evaluated first. The second priority is meant to be a tie-breaker if all other things are equal. That is to say, if all time-related evaluations are the same, this priority can select the grandmaster. If this priority is also a tie, the MAC address is used to select the grandmaster as a last resort.
- d. **Variance:** Clock’s estimate of its own stability based on the existing PTP reference.

The original specification used multicast addresses for IPv4 and IPv6 PTP messaging, but a unicast negotiation option was added later. The packets are UDP encapsulated using port 319 for events and port 320 for general messages. PTP clocks can use unicast or unicast negotiation modes, in addition to multicast. The difference between the unicast options is that unicast mode requires the master to have all of the slaves configured so that it can send “sync” messages to them. Unicast negotiation mode requires slaves to register with the masters by sending negotiation messages, which scales better and is like the classic NTP design (server need not explicitly identify all clients).

The simplest PTP architecture would consist of a single grandmaster clock and several ordinary slave clocks. The ordinary slave clocks would directly reference time from the grandmaster. This would be a “tree” architecture which is simple but has a single point of failure. PTP can also be partially meshed so that other master clocks can peer with one another, like the NTP symmetric mode options. This is more resilient but care must be taken to ensure the grandmaster is properly identified. Sample configurations from Cisco are shown below; notice that the unicast negotiation master does not specify a clock destination since the slave will negotiate its own address as a clock destination. Also note that boundary clocks are only supported in unicast negotiation mode.

```
!! Unicast Negotiation Mode
```

```
! Master Clock
ptp clock ordinary domain 1
tod R0 ntp
input 1pps R0
clock-port MASTER master
transport ipv4 unicast interface loopback 0 negotiation
```

```
! Slave clock
ptp clock ordinary domain 1
tod R0 ntp
output 1pps R0
clock-port SLAVE slave
transport ipv4 unicast interface loopback 0 negotiation
clock source 10.1.1.1
```

```

! Boundary clock
ptp clock boundary domain 1
clock-port SLAVE slave
transport ipv4 unicast interface loopback 0 negotiation
clock source 10.1.1.1
clock-port MASTER master
transport ipv4 unicast interface loopback 1 negotiation

!! Unicast Mode

! Master Clock
ptp clock ordinary domain 1
tod R0 ntp
input 1pps R0
clock-port MASTER master
transport ipv4 unicast interface loopback 0
clock destination 20.1.1.1

! Slave clock
ptp clock ordinary domain 1
tod R0 ntp
output 1pps R0
clock-port SLAVE slave
transport ipv4 unicast interface loopback 0
clock source 10.1.1.1

```

43.3 Synchronous Ethernet (SyncE)

Synchronous Ethernet allows transferring clock signals over the Ethernet physical layer. Ethernet interfaces that support SyncE should also be capable of generating their own synchronization if the reference is lost (internal timing). The SyncE signal is filtered/regenerated at layer 1 and is expected to achieve clock accuracies of +/- 4.6 parts per million (ppm). The ppm measurement is commonly used for low-level timing details since no crystal is perfect. After 1,000,000 units of time, SyncE Ethernet equipment clocks (EEC) will be at 999,995.4 through 1,000,004.6. This is highly accurate.

SyncE encodes its information in the Ethernet Synchronization Message Channel (ESMC) within an Ethernet frame. The destination MAC of the frame is 0180.c200.0002 and uses ethertype 0x8809 (slow protocols) and deeper within the header lies the ESMC. Notice that Ethernet OAM also uses this Ethertype as it is not specific to SyncE, but any “slow” Ethernet protocols. Not counting the Ethernet encapsulation details, the ESMC is a 4 byte TLV byte that carries a Synchronization Status Message (SSM) code. This is a 4 bit field which carries various codes about the synchronization state of the SyncE network by carrying the quality level (QL). It is also designed to help stop synchronization loops.

SyncE can achieve timing in one of four ways:

1. **External:** The EEC obtains its timing from some external source like GPS. This is used in typical deployments.

2. **Line:** NE obtains time by deriving it from an input signal.
3. **Through:** The TX outputs from one interface are synchronized with the RX inputs of the opposite interface.
4. **Internal:** Typically used when a clock is in the holdover state after losing synchronization. It could also be present when there is no other clock available.

SyncE also supports a tree architecture where there is a single master clock that distributed time downstream to clients. There is a single point of failure but no possibility of a synchronization loop. SyncE can also be deployed in a ring, which provides some redundancy but introduces the risk of a synchronization loop. Last, it can be meshed, like PTP and NTP, but there could be potentially many loops despite the added redundancy. An example SyncE configuration from Cisco is shown below.

```
interface GigabitEthernet0/0/0
  synchronous mode
  clock source line
  clock wait-to-restore 720

interface GigabitEthernet1/0/0
  synchronous mode
  clock source line

network-clock synchronization automatic
network-clock input-source 1 external 0/0/0 2m
network-clock input-source 2 external 1/0/0 2m

network-clock output-source line 1 interface GigabitEthernet0/0/0 external
0/0/0 2m
network-clock output-source line 1 interface GigabitEthernet1/0/0 external
1/0/0 2m
```

44. Describe, implement, and troubleshoot SNMP traps, RMON, EEM, and EPC

This section covers some traffic capturing and troubleshooting tools used by many kinds of networks. The network diagram used here is similar to that used in CPP/LPTS. The significant difference is that BGP has been removed from CSR5/CSR7 as CSR7 now gets a DHCP-issued address from CSR5. CSR7 represents a residential customer router for demonstrating advanced EEM. The OOBM laptop simulator, CSR9, now represents an SNMP server within the OOBM network.

Additional Reading – Reference configurations "cap-alarms"

44.1 SNMP traps

This section will focus heavily on SNMP traps and informs. SNMP polling is briefly examined in the security and IP SLA sections. The entire purpose of SNMP traps is to asynchronously notice a network management system (NMS) that some event has occurred. This is an unsolicited message that a device generates and sends without having received an SNMP poll. The fundamental difference between traps and informs is that informs must be acknowledged by the NMS. SNMPv2 introduced informs initially as this was not considered for the initial SNMPv1 rollout. We will first configure SNMPv2c (v2 with community string support) on XRV1 and CSR5. Note: Using the XE command "snmp-server enable traps" enables all traps the device supports. This is typically not appropriate; it is recommended to select the most important traps for your environment. Below is a reasonable example. We specify mostly traps that relate to MPLS L3VPN, including some IGP/BGP information. We can also specify which traps are sent to which servers; in this case, any IGP-related traps are sent to the IPv6 server, while BGP/LDP/MPLS traps are sent to the IPv4 server. Because the trap source is in a VRF, it is assumed that the destination route lookup on the SNMP trap/inform will be conducted in that VRF.

```
! CSR5
snmp-server trap-source GigabitEthernet1
snmp-server contact nrusso
snmp-server enable traps bgp state-changes
snmp-server enable traps isis
snmp-server enable traps mpls ldp session-up session-down
snmp-server enable traps mpls traffic-eng
snmp-server enable traps mpls vpn vrf-up vrf-down
snmp-server host FD00:10:31:5::209 vrf MGMT informs version 2c
  INFORM_COMM_STR isis
snmp-server host 10.31.5.209 vrf MGMT version 2c TRAP_COMM_STR bgp mpls-ldp
  mpls-traffic-eng mpls-vpn
```

We can confirm the configuration by viewing the hosts. The “host” in this context refers to the SNMP server, or NMS, that will be receiving the traps/informs.

```
R5#show snmp host
Notification host: FD00:10:31:5::209    udp-port: 162    VRFName: MGMT    type:
inform
user: INFORM_COMM_STR    security model: v2c

Notification host: 10.31.5.209    udp-port: 162    VRFName: MGMT    type: trap
user: TRAP_COMM_STR    security model: v2c
```

If we clear the IS-IS neighbors, CSR5 tries to send SNMP informs (which require acknowledgements) to the NMS using its IPv6 address. The requests are transmitted once every minute by default. The retry counter is 3 by default, resulting in 4 total informs when unacknowledged. Using “debug snmp packets”, we can see the packets originated by the device.

```
R5#clear isis *

R5#debug snmp packet
SNMP : Packet sent via UDP to FD00:10:31:5::209.162
SNMP: Inform request, reqid 1, errstat 0, erridx 0
  sysUpTime.0 = 36189655
  snmpTrapOID.0 = ciiAdjacencyChange
  ciiNotificationEntry.13 = 2
  ciiCircEntry.2 = 18
  ciiNotificationEntry.1 = 00 00 00 00 00 06 00 00
  ciiNotificationEntry.9 = 1
```

Clearing IS-IS again generates new inform requests, each of which expires after one minute. They are generated about 1 second apart.

```
R5#clear isis *
R5#show snmp pending
req id: 29, dest: 7FB3150DC7F0, V2C community: INFORM_COMM_STR, Expires in 56 secs
req id: 30, dest: 7FB3150DC7F0, V2C community: INFORM_COMM_STR, Expires in 56 secs
req id: 31, dest: 7FB3150DC7F0, V2C community: INFORM_COMM_STR, Expires in 57 secs
req id: 32, dest: 7FB3150DC7F0, V2C community: INFORM_COMM_STR, Expires in 58 secs
```

We can tune this more aggressively to ensure the router doesn’t keep sending the message minutes after an event has occurred. In this case, the router will send a single inform and wait 5 seconds for a reply.

```
! CSR5
snmp-server inform timeout 5
snmp-server inform retries 0
```

Clearing LDP neighbors has a similar affect, except these are traps sent to the IPv4 server. There are no retransmissions or acknowledgements for traps; they are “fire and forget” messages. Notice that this trap is more verbose/readable than the IS-IS one. We can even see the up/down messages and TCP session endpoints in the message body. If we check for any pending replies, there are none, as traps are not acknowledged. We also see the SNMP interface ID of 19, which is the link facing XRv11. This shows where the neighbor failed.

```
R5#clear mpls ldp neighbor 23.0.0.11
%LDP-5-CLEAR_NBRs: Clear LDP neighbors (23.0.0.11) by console

R5#show snmp pending
[no output]

R5#show snmp mib ifmib ifindex | include 19
GigabitEthernet2.551: Ifindex = 19
```

The XR configuration is very similar. The downside is that there does not appear a way to associate certain traps/informs with a certain NMS, so all NMS' will get all configured traps/informs. In this case, the IPv4 host gets all the information as traps, including the IS-IS information that it didn't get on CSR5.

```
! XRv1
snmp-server vrf MGMT
  host 10.31.5.209 traps version 2 TRAP_COMM_STR
  host fd00:10:31:5::209 informs version 2 INFORM_COMM_STR

snmp-server contact nrusso
snmp-server trap-source MgmtEth0/0/CPU0/0
snmp-server inform pending 5
snmp-server inform retries 0

snmp-server traps mpls ldp up
snmp-server traps mpls ldp down
snmp-server traps mpls l3vpn vrf-up
snmp-server traps mpls l3vpn vrf-down
```

For XRv1, we will do verification in a less destructive way. We can enable the ordinary SNMP packet debugging, as well as debugging for “test-trap” messages that we locally generate. XE also has the ability to use the “test” command for SNMP trap generation, but we demonstrate it on XR since the behavior is similar. We enable both debugs, then generate a trap to signal an LDP “session-down” event.

```
RP/0/0/CPU0:XRv1#debug snmp test-trap
RP/0/0/CPU0:XRv1#debug snmp packet
RP/0/0/CPU0:XRv1#snmp test trap routing mpls ldp session-down
```

First, the “test-trap” debugs show their output from the software processing of the test trap. Apparently this test command selected CSR5 as the neighbor to fake as being down for the purposes of reporting (probably because it had the least uptime since we flapped it earlier). The output is verbose but the message is clear.

```

```

Shortly thereafter, the real SNMP packet debug shows that the packets were actually sent to the NMS' configured. We can see the trap-source being set properly, as we configured.

```

! XRv1
RP/0/0/CPU0:snmpd[1128]: t11 snmp_trap_addr_get:snmp trap-source configured
:fd00:10:31:5::211

RP/0/0/CPU0:snmpd[1128]: t11 snmp_send_pdu_udp_transport: Q-ing TRAP[sp 161,
dp 41472]
RP/0/0/CPU0:snmpd[1128]: t11 snmp_trap_addr_get:snmp trap-source configured
:10.31.5.211
RP/0/0/CPU0:snmpd[1128]: t11 SENT[I] 238 bytes to fd00:10:31:5::209:162 from
fd00:10:31:5::211:162, vrfid 0x60000003, tblid 0xe0800012
RP/0/0/CPU0:snmpd[1128]: t11 SENT[T] 236 bytes to 10.31.5.209:162 from
10.31.5.211:161, vrfid 0x60000003, tblid 0xe0000012

```

One oddity is that XRv reports the source-port of the inform is 162 and the source-port of the trap is 161, but we expected both to have dest-ports of 162. However, the end of the debug shows us that the ports were set properly at the last second. This is probably just a cosmetic debug issue or an internal software operation. Notice SENT[I], meaning inform, was sent to the IPv6 host, while SENT[T] (trap), was sent to the IPv4 host. This is the expected behavior.

SNMPv3 traps are very similar. This is a more secure model of SNMPv3 that is examined in detail, from a security perspective, in the security section. The only difference is that instead of assigning a community string to an SNMP server, you assign a user. CSR6 uses authentication only (no encryption) while XRv2 uses both. For brevity, we will only configure these routers to report link-up and link-down events, both of which can be “simulated” on both XE and XR.

```

! CSR6
snmp-server group AUTH_GROUP v3 auth
snmp-server contact nrusso
snmp-server enable traps snmp linkdown linkup
snmp-server host 10.31.5.209 vrf MGMT traps version 3 auth JLI
snmp-server host FD00:10:31:5::209 vrf MGMT informs version 3 auth JLI
! The following line does not show in the running-config
snmp-server user JLI AUTH_GROUP v3 auth sha AUTHPASS

! XRv2
snmp-server vrf MGMT
  host 10.31.5.209 traps version 3 priv NRUSSO
  host fd00:10:31:5::209 informs version 3 priv NRUSSO

notifyview:
row status: active

```

```

RP/0/0/CPU0:XRv2#show snmp users
User Name: NRUSSO

```

```
EngineId: localSnmplD
storage-type: nonvolatile      active
```

Using the “test” command along with “debug snmp packet”, we will ensure CSR6 sends traps/informs to its configured NMS’. This time, both NMS’ should get notified of an event since I did not specify per=host traps/informs when configuring the servers. Oddly, SNMPv3 test informs don’t seem to work on XE. I only see traps being generated. For SNMPv2c, the “test traps” on XR also included informs.

```
R6#debug snmp packet
R6#test snmp trap snmp linkdown
Generating Link Down trap

! CSR6
SNMP: Queuing packet to 10.31.5.209
SNMP: V2 Trap, reqid 12, errstat 0, erridx 0
sysUpTime.0 = 29336782
snmpTrapOID.0 = snmpTraps.3
ifIndex.1 = 1
ifDescr.1 = GigabitEthernet1
ifType.1 = 6
lifEntry.20.1 = Link Down Trap
SNMP: Packet sent via UDP to 10.31.5.209
```

SNMPv3 does not appear to work on XRv; with traps or informs, I see neither one generated during the test. The OS acknowledges the trap but does not appear to put a packet on the wire.

```
RP/0/0/CPU0:XRv2#snmp test trap interface link-down
RP/0/0/CPU0:: test_trap[65713]: Debug init Done
RP/0/0/CPU0:: test_trap[403]: Trap ID: 4
RP/0/0/CPU0:: test_trap[403]: make_test_traps: input args 0x0 0x0 (null)
(null)
RP/0/0/CPU0:: test_trap[403]: Sending LinkDown Trap for ifIndex :1
```

44.2 Remote Monitor (RMON) in XE and logging correlation in XR

RMON is a simple way to generate alarms (log messages, traps, etc) when certain thresholds are crossed. Common uses for this are measuring CPU utilization, interface load, and any arbitrary SNMP MIB parameter. Some switches support RMON at the interface level for traffic measuring/discovery of sorts, but routers typically do not. RMON is comprised primarily of two components: events and alarms. An event is assigned a number determines “what to do” when an alarm is tripped. These events don’t actually measure anything, they are really more like “actions” than events. RMON alarms measure a specific SNMP variable against rising and/or falling threshold, and invoke an RMON event when either threshold is crossed.

First, we will define some events (which are like actions). These are not tied to any alarms yet, and we can reuse them across many alarms. Event 1 creates a syslog message and sends a trap to the

configured SNMP servers (SNMP must be configured already). The second event issues a log message and specifies a process owner and description. We can view the events with a simple command shown below. Don't worry about the timers/log entries yet.

```
! CSR6
rmon event 1 log trap JLI
rmon event 2 log description "EVENT 2 WAS CALLED" owner nrusso
```

```
R6#show rmon events
Event 1 is active, owned by nrusso
Description is
Event firing causes log and trap to community JLI,
last event fired at 0y0w5d,23:21:02,
Current uptime      0y0w5d,23:24:15
Current log entries:
  index  uptime              description
  1      0y0w5d,23:21:02
```

```
Event 2 is active, owned by nrusso
Description is EVENT 2 WAS CALLED
Event firing causes log,
last event fired at 0y0w5d,23:13:46,
Current uptime      0y0w5d,23:24:15
Current log entries:
  index  uptime              description
  1      0y0w5d,23:13:46      EVENT 2 WAS CALLED
```

Next, we will define some alarms. There are “alarms” and “hc-alarms”. The only difference is that HC (high capacity) alarms are used to measure 64 bit values, while regular alarms measure 32 bit values. Cisco states that interfaces less than 20 Mbps in speed must use 32 bit objects, interfaces between 20 Mbps and 650 Mbps can use either 32 or 64 bit objects, and interfaces greater than 650 Mbps must use 64 bit objects. In our case of having all Gigabit Ethernet interfaces, we “should” use 64 bit values but 32 bit values also seem to work. We will define an HC-alarm to measure input bytes on the interface towards CSR5. First, we must determine the interface by looking at the SNMP ifmib to see how interfaces have been enumerated by SNMP.

```
R6#show snmp mib ifmib ifindex | include 556
GigabitEthernet2.556-mpls layer: Ifindex = 19
GigabitEthernet2.556: Ifindex = 18
```

We will now configure SNMP to “remember” those interface assignments across reloads, otherwise RMON is worthless. When the router reloads, these SNMP ifmib indices may change unless we issue the command below.

```
! CSR6
snmp ifmib ifindex persist
```

Last, we create the RMON hc-alarm. There are several numerical components in the alarm highlighted in different colors for clarity. The first number is the alarm ID, which is an arbitrary number (yellow) used to reference the alarm. The number following the object to monitor is the sample rate in seconds; this is how often the device polls the counter to perform measurements (cyan). The “delta” option means that the operation should compare the new measurement against the previous one; “delta” is typically used to measure values that only move in one direction (things that only increase or decrease, NOT rates). The rising-threshold and falling-threshold values represent hexadecimal numbers whereby the alarm is triggered when the sampled data is above or below the configured threshold, respectively (pink). In this case, if the input bytes is more than 16384 (0x4000) bytes in a 10 second period, the rising-threshold is triggered. When it falls below 8192 (0x2000) bytes in a 10 second period, the falling-threshold is triggered. The “actions” taken when those thresholds are crossed are the RMON events defined earlier (green). We can tie in different actions when each threshold is crossed, as shown below.

```
! CSR6
rmon hc-alarm 10 ifHCInOctets.18 10 delta rising-threshold 04000 1 falling-
threshold 02000 2 owner nrusso
```

We can verify the configuration of the alarm using a simple command. Notice that it displays the thresholds in decimal, which is convenient for humans trying to troubleshoot RMON. Unfortunately, this show command doesn’t show you the HC-alarm ID (number 10 in yellow above), so if you had many alarms, you cannot easily differentiate them with this command.

```
R6#show rmon hc-alarms
Monitors ifHCInOctets.18 every 10 second(s)
Taking delta samples, last value was 3291
Rising threshold Low is 16384, Rising threshold Hi is 0,
    assigned to event 1
Falling threshold Low is 8192, Falling threshold Hi is 0,
    assigned to event 2
On startup enable rising or falling alarm
```

On CSR5, we will begin flooding pings to CSR6 to trip the rising-threshold (not shown). We can see the syslog message and subsequent SNMP trap (using “debug snmp packet”) when this event is triggered. Despite having only SNMPv3 configured, the trap is sent as SNMPv2c, and I cannot find a way to change this. It is also only sent to the IPv4 server, presumably because the IPv6 server is only sending informs, and perhaps the RMON process can only generate literal traps. We can see the hex value 0x4816 (decimal 18454) corresponds with the actual input bytes measured, which is greater than 0x4000, the rising-threshold.

```
! CSR6
%RMON-5-HCRISINGTRAP: Rising trap is generated because the value of
ifHCInOctets.18 exceeded the rising-threshold hc value 16384
```

```

SNMP: Queuing packet to 10.31.5.209
SNMP: V2 Trap, reqid 18, errstat 0, erridx 0
  sysUpTime.0 = 51606242
  snmpTrapOID.0 = hcAlarmMIB.2.0.1
  hcAlarmIndex.10 = 10
  hcAlarmVariable.10 = ifHCInOctets.18
  hcAlarmSampleType.10 = 2
  hcAlarmAbsValue.10 = 0x000004816
  hcAlarmRisingEventIndex.10 = 16384
  hcAlarmRisingThreshAbsValueLo.10 = 16384
  hcAlarmRisingThreshAbsValueHi.10 = 0
  hcAlarmRisingThresholdValStatus.1 = 2
SNMP: Packet sent via UDP to 10.31.5.209

```

When CSR5 stops bursting traffic, the RMON alarm will fall below the falling-threshold and trigger event 2. This only creates a syslog with no SNMP trap.

```

! CSR6
%RMON-5-HCFALLINGTRAP: Falling trap is generated because the value of
ifHCInOctets.18 has fallen below the falling-threshold hc value 8192

```

Every time a threshold is crossed and an event is referenced, RMON keeps track of when it was called and stores it in memory. We can see that information by looking at the RMON events again. I have tripped the threshold several times while testing, which is why there are so many log entries per event. Notice there is no description with event 1 log entries, but there is with event 2.

```

R6#show rmon events
Event 1 is active, owned by nrusso
Description is

  2      0y0w5d,23:18:53      EVENT 2 WAS CALLED
  3      0y0w5d,23:23:21      EVENT 2 WAS CALLED
  4      0y0w5d,23:40:11      EVENT 2 WAS CALLED

```

The next example shows measuring bandwidth on the same interface (Gig2.556). This might be valuable if there is some NMS or automation system that changes interface bandwidth as a way to adjust QoS shapers or IGP convergence semi-dynamically. Since the SNMP parameters are not always obvious, one would have to know in advance what the OID is for a given parameter, or reference the documentation. We will reuse RMON events 1 and 2 just to show that it can be done, but new events can be customized per RMON alarm. Notice this is a regular RMON alarm since the HC counters are typically limited to interfaces (in/out bytes, packets, etc). The alarm ID is 20 (yellow) and since we are sampling a rate (a value that doesn't always increase or decrease), we use the absolute method. The rising-threshold is 800 Mbps and falling-threshold is 700 Mbps, where crossing either one fires event 1 or 2, respectively.

```
! CSR6
rmon alarm 20 ifSpeed.18 10 absolute rising-threshold 800000000 1 falling-
threshold 700000000 2
```

We can verify the alarm was configured properly by looking at RMON alarms. Unlike HC-alarms, we can see the alarm-ID, which is valuable. Notice that failing to specify an owner defaults to using "config" as opposed to a specific user (grey).

```
R6#show rmon alarms
Total number of alarm trap failures 0
Alarm 20 is active, owned by config
Monitors ifSpeed.18 every 10 second(s)
Taking absolute samples, last value was 1000000000
Rising threshold is 800000000, assigned to event 1
Falling threshold is 700000000, assigned to event 2
On startup enable rising or falling alarm
```

When we configure this alarm, RMON evaluates the current state of the interface and sees its speed is 1 Gbps. This crosses the rising threshold, so event 1 is fired. This creates a syslog message and SNMP trap.

```
! CSR6
%RMON-5-RISINGTRAP: Rising threshold has been crossed because the value of
ifSpeed.18 exceeded the rising-threshold value 800000000
SNMP: Queuing packet to 10.31.5.209
SNMP: V2 Trap, reqid 24, errstat 0, erridx 0
sysUpTime.0 = 51898167
snmpTrapOID.0 = rmon.0.1
alarmEntry.1.20 = 20
alarmEntry.3.20 = ifSpeed.18
alarmEntry.4.20 = 1
alarmEntry.5.20 = 1000000000
alarmEntry.7.20 = 800000000
SNMP: Packet sent via UDP to 10.31.5.209
```

When we change the bandwidth to a lower value, when RMON sees this again (based on sample interval), it will trigger the falling-threshold event. Only the syslog message is generated.

```
! CSR6
interface GigabitEthernet2.556
 bandwidth 123456
```

```
%RMON-5-FALLINGTRAP: Falling threshold has been crossed because the value of
ifSpeed.18 has fallen below the falling-threshold value 700000000
```

```
R6#show rmon alarms
Total number of alarm trap failures 0
Alarm 20 is active, owned by config
Monitors ifSpeed.18 every 10 second(s)
Taking absolute samples, last value was 123456000
Rising threshold is 800000000, assigned to event 1
Falling threshold is 700000000, assigned to event 2
On startup enable rising or falling alarm
```

Because events are shared across multiple alarms, any alarm triggered that event gets added to the event log. This can complicate troubleshooting as events and alarms are not mapped 1:1. For example, on event 2, index 4, this was the last time we tested the HC-alarm with packet counters. Several minutes later, we began testing the bandwidth measurement, which added new entries to the same log.

```
R6#show rmon events | begin Event_2
Event 2 is active, owned by nrusso
Description is EVENT 2 WAS CALLED
Event firing causes log,
last event fired at 0y0w6d,00:11:40,
Current uptime      0y0w6d,00:14:25
Current log entries:
  index  uptime                description
  1      0y0w5d,23:13:46      EVENT 2 WAS CALLED
  2      0y0w5d,23:18:53      EVENT 2 WAS CALLED
  3      0y0w5d,23:23:21      EVENT 2 WAS CALLED
  4      0y0w5d,23:40:11      EVENT 2 WAS CALLED
  5      0y0w6d,00:00:36      EVENT 2 WAS CALLED
  6      0y0w6d,00:02:27      EVENT 2 WAS CALLED
  7      0y0w6d,00:02:37      EVENT 2 WAS CALLED
  8      0y0w6d,00:10:51      EVENT 2 WAS CALLED
  9      0y0w6d,00:11:40      EVENT 2 WAS CALLED
```

XR logging correlation is a sizable topic with many fancy options. It is sometimes referred to as a subcomponent of the IOS XR Alarm Management and Debugging Event System (ALDEMS). We will examine the basic configuration and perform detailed verification; this is the closest thing to RMON I can find within XR. The general idea is to correlate logging messages that are related to the same event. For example, if the interface between XRv1 and CSR5 fails, this will trigger a link-down message. It will

also trigger an IS-IS neighbor down, LDP neighbor down, and possibly BGP neighbor down. We probably don't need to see all four of these messages, since the root-cause of the issue was the interface failing, which allows administrators to focus troubleshooting efforts. We know it is not a problem specific to IGP, LDP, or BGP. To simulate this, I will first configure basic remote logging on XRv1 to send messages to CSR9. I also enable logging for IS-IS, LDP, and the link in question, as these are disabled by default.

```
! XRv1
logging 10.31.5.209 vrf MGMT severity info

interface GigabitEthernet0/0/0/0.551
  logging events link-status

mpls ldp
  log
  neighbor

router isis 23
  log adjacency changes
  log pdu drops
```

Next, I will shut down the subinterface towards CSR5. Notice that the IS-IS and LDP neighbors go down immediately, but the BGP peer stays up because of an alternate IGP path via XRv2. This may not always be the case (for example, XRv2's link to CSR6 is down), but we can still identify the potential BGP failure as a by-product of the link failure. In this example, we assume the BGP failure was also related to this link-down event.

```
! XRv1
ifmgr[225]: %PKT_INFRA-LINK-5-CHANGED : Interface GigabitEthernet0/0/0/0.551,
changed state to Administratively Down

isis[1010]: %ROUTING-ISIS-5-ADJCHANGE : Adjacency to R5
(GigabitEthernet0/0/0/0.551) (L2) Down, Interface state down

mpls_ldp[1048]: %ROUTING-LDP-5-NBR_CHANGE : VRF 'default' (0x60000000),
Neighbor 23.0.0.5:0 is DOWN (Interface state down)
```

As an example, the BGP looks like this. This is not part of the current test, but here for reference.

```
bgp[1052]: %ROUTING-BGP-5-ADJCHANGE : neighbor 23.0.0.5 Down - BGP
Notification sent, hold time expired (VRF: default) (AS: 23)
```

XRv1 is currently sending all of these logs to CSR9. CSR9 is using EPC inbound on its OOBM management interface. Looking at the packet dumps, we can see those three syslog messages arrive at CSR9: interface, IS-IS, and LDP failure messages.

```
R9#show monitor capture CAP buffer dump
```

```

Before continuing, we will no-shutdown this interface on XRv1 to bring the network back online (not shown).

```
RP/0/0/CPU0:XRv1#show interfaces gig0/0/0/0.551 brief
```

Intf Name	Intf State	LineP State	Encap Type	MTU (byte)	BW (Kbps)
Gi0/0/0/0.551	up	up	802.1Q	1518	1000000

It would be convenient if the administrator could correlate these logs as treat them like a single event. It is important to quantify what constitutes a single event; for example, an interface going down and the BGP peer failing 3 hours later are probably not related. For this reason, we specify a timeout (ms) whereby the counter begins when the first log message is seen. The first message does not have to be the root-cause (the interface down event), but naturally, it often is. When specifying the alarms, the format is CATEGORY/GROUP/CODE. The format of a syslog is always CATEGORY-GROUP-SEVERITY-CODE. For example, "MGBL-SYS-5-CONFIG_I" and "ROUTING-LDP-5-NBR_CHANGE" both have hyphens to separate the fields. The logging correlator does not look at the severity. The rule below shows all four messages broken up by CATEGORY/GROUP/CODE with spaces in between as the parser requires. The timeout is set to 300000 ms, or 300 seconds, or 5 minutes.

```
! XRv1
logging correlator rule LINK_DOWN type nonstateful
  timeout 300000
  rootcause PKT_INFRA LINK CHANGED
  nonrootcause
    alarm ROUTING BGP ADJCHANGE
    alarm ROUTING ISIS ADJCHANGE
    alarm ROUTING LDP NBR_CHANGE
```

We can verify the rule was configured properly using basic show commands. The root-cause has a "root" code type while the others are considered "leaf". The difference between non-stateful and stateful rules is as follows. Non-stateful rules prevent all leaf messages from going to the syslog server, at any point, assuming the correlation occurs (i.e., the root-cause is seen). The leaf messages only remain in the correlation buffers. Stateful rules allows leaf messages to go to the syslog process if the root-cause alarm clears, which is useful for detecting non-root-cause conditions even after the root-cause is no longer present.

```
! XRv1
RP/0/0/CPU0:XRv1#show logging correlator rule LINK_DOWN
Rule Name : LINK_DOWN
Type      : Non Stateful
Source    : User
Timeout   : 300000          Rule State: RULE_APPLIED_ALL
Rootcause Timeout : None
Context Correlation : disabled
Reissue Non Bistate : N/A
Reparent  : N/A
Alarms :
```

Code	Type:	Category	Group	Message
	Root:	PKT_INFRA	LINK	CHANGED
	Leaf:	ROUTING	BGP	ADJCHANGE
	Leaf:	ROUTING	ISIS	ADJCHANGE
	Leaf:	ROUTING	LDP	NBR_CHANGE

```

Apply Locations:      None
Apply Contexts:      None

```

Number of buffered alarms : 0

These rules can be applied directly to the router or subcomponents therein. In XRv, it doesn't make sense to do anything other than "all-of-router", so we do that. We can also put the rule inside of a ruleset to achieve greater scalability when making multiple rules for a single location. Although we only have one rule (no benefit to rulesets), I use this configuration method anyway. More rules could be added to "LINK_RULESET" later.

```

! XRv1
logging correlator ruleset LINK_RULESET
  rulename LINK_DOWN

logging correlator apply ruleset LINK_RULESET
  all-of-router

```

We can verify that the ruleset has been applied, and also quickly see how many messages are in the correlation buffer. Presently, it is empty, as we expect.

```

RP/0/0/CPU0:XRv1#show logging correlator ruleset LINK_RULESET
Rule Set Name :   LINK_RULESET
Rules: LINK_DOWN                               : Applied

RP/0/0/CPU0:XRv1#show logging correlator info
Buffer-Size      Percentage-Occupied
655360           0.00

```

Next, we shut down the link again. Notice that only one message is sent to the syslog server. We only see the root cause; the leaf messages are never sent to the syslog process internal to XRv1 for nonstateful rules (assuming root cause is seen) and are instead stored in the correlation buffer. Since this is the only log message sent to syslog, we verify on CSR9 that no other logs were received. CSR9 is not explicitly told that IS-IS and LDP also failed as those are non-root-cause events.

```

! XRv1

```

As a preliminary check, we can check the correlation buffer utilization again to ensure the “Percentage-Occupied” is not 0.0 anymore. We should have some information present.

```

RP/0/0/CPU0:XRv1#show logging correlator info
Buffer-Size      Percentage-Occupied
655360           0.43

```

There are several ways to check the logs. First, we can look for logging correlations specific to a rule. The output is difficult to read, but the first field is the correlation ID, followed by the sub-log number. The CID is 1, and there are sub logs 1, 2, and 3. We can see 1.1 is the root cause while 1.2 and 1.3 are leaf events. These are all correlated as part of CID 1.

```

RP/0/0/CPU0:XRv1#show logging correlator buffer rule-name LINK_DOWN
#C_id.id:Rule Name:Source :Context:      Time      : Text
RP/0/0/CPU0:XRv1#show logging correlator buffer rule-name LINK_DOWN
#1.1 :LINK_DOWN:RP/0/0/CPU0:              :Aug 22 15:47:41.299
2015:ifmgr[225]: %PKT_INFRA-LINK-5-CHANGED : Interface GigabitEthernet0/0/0/0.551,
changed state to Administratively Down
#1.2 :LINK_DOWN:RP/0/0/CPU0:              :Aug 22 15:47:41.299

#1.3 :LINK_DOWN:RP/0/0/CPU0:              :Aug 22 15:47:41.319
2015:mpls_ldp[1048]: %ROUTING-LDP-5-NBR_CHANGE : VRF 'default' (0x60000000), Neighbor
23.0.0.5:0 is DOWN (Interface state down)

```

Assuming we didn’t know the correlation ID and wanted to find it without looking at the correlation buffer first, we can query the general logging events. Because the root cause was sent to the syslog process, syslog is aware of this one message along with its CID. Searching for string with “Administ” in them, we find a log at the bottom with a number following the colon. This is the CID.

```

RP/0/0/CPU0:XRv1#show logging events buffer all-in-buffer | include Administ
[snip]

```

```
#776      :1      :RP/0/0/CPU0:Aug 22 15:47:41.299 2015:ifmgr[225]: %PKT_INFRA-  
LINK-5-CHANGED : Interface GigabitEthernet0/0/0/0.551, changed state to  
Administratively Down
```

We can also query the correlation buffer based on the CID, if we know it. This output is identical to the output examined earlier, just referenced differently. The root cause is highlighted for clarity. The leaf messages will be in this buffer until manually purged, but CSR9 (syslog server) will never see them.

```
RP/0/0/CPU0:XRv1#show logging correlator buffer correlationID 1  
#C_id.id:Rule Name:Source :Context:                Time                : Text  
#1.1      :LINK_DOWN:RP/0/0/CPU0:                  :Aug 22 15:47:41.299  
2015:ifmgr[225]: %PKT_INFRA-LINK-5-CHANGED : Interface GigabitEthernet0/0/0/0.551,  
changed state to Administratively Down  
#1.2      :LINK_DOWN:RP/0/0/CPU0:                  :Aug 22 15:47:41.299  
2015:isis[1010]: %ROUTING-ISIS-5-ADJCHANGE : Adjacency to R5  
(GigabitEthernet0/0/0/0.551) (L2) Down, Interface state down  
#1.3      :LINK_DOWN:RP/0/0/CPU0:                  :Aug 22 15:47:41.319  
2015:mpls_ldp[1048]: %ROUTING-LDP-5-NBR_CHANGE : VRF 'default' (0x60000000), Neighbor  
23.0.0.5:0 is DOWN (Interface state down)
```

If we repeat the process quickly once more, we see only one syslog appears on XRv1's console. The remaining logs were buffered as we can quickly see by seeing the size of the buffer increase.

```
! XRv1  
:ifmgr[225]: %PKT_INFRA-LINK-5-CHANGED : Interface  
GigabitEthernet0/0/0/0.551, changed state to Administratively Down
```

```
RP/0/0/CPU0:XRv1#show logging correlator info  
Buffer-Size      Percentage-Occupied  
655360           0.86
```

We can determine the correlator ID by looking at the syslog buffer, and then check the correlation buffer for the entries within that CID. Over time, looking at the buffer by rulename will not scale since each event is a separation correlation (provided they are not inside of one another's timeout window).

```
RP/0/0/CPU0:XRv1#show logging events buffer last 50 | include PKT_INFRA-LINK  
#836      :3      :RP/0/0/CPU0:Aug 22 16:19:04.860 2015:ifmgr[225]: %PKT_INFRA-  
LINK-5-CHANGED : Interface GigabitEthernet0/0/0/0.551, changed state to  
Administratively Down
```

```
RP/0/0/CPU0:XRv1#show logging correlator buffer correlationID 3  
#C_id.id:Rule Name:Source :Context:                Time                : Text

23.0.0.5:0 is DOWN (Interface state down)
```

When non-root-cause messages are caused by events outside the scope of the root cause message, they still get forced into the correlation buffer. During this “purgatory” period, the router waits for the specified timeout for the root-cause to occur. As an example, flapping CSR5’s interface to XRv1 a few times creates several IS-IS/LDP messages that are not related to an interface flap on XRv1’s side. To XRv1, these could be legitimate IS-IS/LDP issues since its interface is stable. The correlation buffer shows 6 logs, all correlated under CID 4, with no root cause. A quick way to tell is that the category for all of these rules is ROUTING, where the PKT_INFRA is the category of the root-cause for this particular correlation rule.

```
RP/0/0/CPU0:XRv1#show logging correlator buffer rule-name LINK_DOWN

```

Once the timeout expires (up to 5 minutes), all of these logs will be sent to the syslog process in order. Syslog directs them to the console and to the remote logging host, CSR9. They are all printed in quick succession, so in the event of LPTS (on a hardware router), ensure that any outbound syslog-related policers account for bursty syslog traffic towards the syslog server.

```
! XRv1
isis[1010]: %ROUTING-ISIS-5-ADJCHANGE : Adjacency to R5
(GigabitEthernet0/0/0/0.551) (L2) Up, New adjacency

```

```
mpls_ldp[1048]: %ROUTING-LDP-5-NBR_CHANGE : VRF 'default' (0x60000000),  
Neighbor 23.0.0.5:0 is UP (IPv4 connection)
```

The entries are removed from the correlator buffer at this point. There was no real correlation since the root-cause was never seen in conjunction with the leaf messages.

```
RP/0/0/CPU0:XRv1#show logging correlator buffer correlationID 4  
NO records matching query found
```

If you need to clean out the correlator buffer to make extra space, you can do so selectively per CID or simply erase everything.

```
RP/0/0/CPU0:XRv1#clear logging correlator delete ?  
<0-4294967294> Correlation ID  
all-in-buffer Delete all messages
```

Alternatively, you can adjust the buffer size if space is running low. I do the opposite (to save memory) and shrink it significantly. As a result, the buffer is almost 70% full despite having only a few correlations.

```
RP/0/0/CPU0:XRv1(config)#logging correlator buffer-size 8192
```

```
RP/0/0/CPU0:XRv1#show logging correlator info  
Buffer-Size      Percentage-Occupied  
8192              69.14
```

44.3 Embedded Event Manager (EEM)

EEM is a lightweight, in-line scripting tool built into the XE and XR for automating certain tasks on the router. It can match a variety of inputs (CLI commands, syslog, counters, timers, IP SLA events, tracked objects, etc) and perform a variety of actions (CLI actions, syslog, counter increment/decrement, IP SLA probes, etc). We will look at some examples on XE only since XR does not have an applet feature; all of its scripts are actual TCL files which I assume is beyond the scope of CCIE SP.

The first example is on CSR5. The goal is to convince the network administrator to use “show running-config” less in an effort to learn more advanced commands. After using show run three times, a syslog message tells the user to use it less often. Two scripts are used; one counts the number of “show run” commands, and the other tests for that timer equaling 3, and then prints a log message. A note on EEM sync is warranted. With sync enabled, the EEM applet runs before the original command is executed. Sync disabled means the two run in parallel. The only time EEM applets need sync is when the command

being entered is going to generate output that the script cares about. When not using sync, you can optionally skip the command altogether, which means it never gets issued. In our case, whether the router increments the counter first or issues the “show run” command first is not relevant since the two happen at almost the exact same time. The second script tracks the counter equaling 3; when it does, the syslog message is issued and the timer is reset to 0.

```
! CSR5
event manager applet MATCH_SHOW_RUN
  event cli pattern "show run" sync no skip no
  action 020 counter name "SHOW_RUN_COUNTER" op inc value 1

event manager applet YELL_AT_USER
  event counter name SHOW_RUN_COUNTER entry-val 3 entry-op eq exit-val 0 exit-
op eq
  action 010 syslog priority critical msg "Stop using show run all the time"
  action 020 counter name "SHOW_RUN_COUNTER" op set value 0
```

We can test it by issuing “show run” three times. Notice that the EEM script expands the entire command, and the parser does too, so any short-hand command used is still matched.

```
R5#show run | include nothing
R5#show running | include nothing
R5#sh running-config | include nothing
%HA_EM-2-LOG: YELL_AT_USER: Stop using show run all the time
```

Using EEM debugs, we can see the counter increment when show run is issued. Currently, the counter is at 2. The next stanza shows it at 3, which triggers the entrance criteria based on our counter to create a syslog message. The script resets the counter to 0 before exiting.

```
R5#debug event manager policydir
EEM: policy_dir xml builtin: name:_cli_msg value:show running-config
fh_fd_counter_event_modify: re=0x7FB3151CE480
*** thresh_val = 3, exit_thresh_val 0
*** current_val = 2, monitored = 1

EEM: policy_dir xml builtin: name:_cli_msg value:show running-config
fh_fd_counter_event_modify: re=0x7FB3151CE480
*** thresh_val = 3, exit_thresh_val 0
*** current_val = 3, monitored = 0

EEM: policy_dir xml builtin: name:_counter_name value:SHOW_RUN_COUNTER
fh_fd_counter_event_modify: re=0x7FB3151CE480
*** thresh_val = 3, exit_thresh_val 0
*** current_val = 0, monitored = 1
```

The next set of scripts on CSR5 will check for a route to 23.0.0.12/32. If this exact route is not reachable, an SNMP trap and email will be sent to the NMS. This could be useful on a platform that is running a feature that the built-in SNMP traps don't natively support in the parser. There are many other EEM scripts to solve this, but I am making it complicated intentionally. The first script tracks an IP SLA to see if XRv2's loopback is responding. If it's not, the script does a "show ip route" and displays the output to the user. Then, it publishes an application event to a specific sub-system that a second script looks for as an event. The second script notifies the NMS of the fault. This basic software engineering hierarchy could allow many different "check route" scripts to invoke the same "notify" script rather than define the notification action themselves. Note that we also have to update our SNMP configuration to send EEM traps; we will send them to the IPv6 SNMP server only.

```
! CSR5
snmp-server enable traps event-manager
snmp-server host FD00:10:31:5::209 vrf MGMT informs version 2c
INFORM_COMM_STR isis event-manager

event manager applet CHECK_ROUTE_XRV12
  event track 1 state down
  action 005 cli command "enable"
  action 010 cli command "show ip route 23.0.0.12"
  action 020 puts "$_cli_result"
  action 030 publish-event sub-system 12 type 2012 arg1 "route lost"

event manager applet NOTIFY_NMS
  event application sub-system 12 type 2012
  action 010 snmp-trap strdata "LOST_ROUTE_XRV12"
  action 020 mail server "10.31.5.209" to "nrusso@ccie.sp" from "r5@ccie.sp"
  subject "LOST_ROUTE_XRV2" source-interface GigabitEthernet1 vrf MGMT

track 1 ip sla 1 reachability

ip sla 1
  icmp-echo 23.0.0.12 source-ip 23.0.0.5
  threshold 1000
  timeout 1000
  frequency 1
ip sla schedule 1 life forever start-time now
```

To trigger the event, I add a null route for XRv2's loopback to CSR5. With EEM debugs enabled, we can see most of the activity. First, EEM enters privileged-exec mode to issue the "show ip route" command. It then prints this string to the console. Normally, the output would be "Network not in table" but adding the null route returns a matching /32, as expected.

```
! CSR5
ip route 23.0.0.12 255.255.255.255 null0
```

```

R5#debug event manager action cli
%TRACK-6-STATE: 1 ip sla 1 reachability Up -> Down
%HA_EM-6-LOG: CHECK_ROUTE_XRV12 : DEBUG(cli_lib) : : CTL : cli_open called.

```

The last set of scripts will go on CSR7. This is now a DHCP client which represents a residential router connected directly to a PE at layer 3. The PE is the DHCP server, but the customer wants to dynamically update inbound ACLs based on the IP address assigned by the SP. The customer is running NAT, and since inbound ACLs are processed first, almost all of the traffic arriving for CSR7's LAN will be destined for the outside address. There are several complex ACLs/object-groups that are meant to increase security to allow common residential services, such as web browsing, SSH, DNS, and IPSec. Using the regexp action, we can capture values from within parenthesis and store them in variables. The regexp is applied against a string (in our case, the result from the CLI) and we use this to parse valuable output.

```
! CSR7
event manager applet UPDATE_WAN_IP
  event none sync yes
  action 100 cli command "enable"
  action 110 cli command "show ip interface brief | include
GigabitEthernet2.557"
  action 120 regexp " ([0-9.]+) " "$_cli_result" IP_REGEX CUR_IP_ADDR
  action 130 cli command "show ip access-list WAN_IN | include OBJGRP"
  action 140 regexp "per.* ([0-9.]+)" "$_cli_result" ACL_REGEX ACL_IP_ADDR
```

```

action 150 string equal "$CUR_IP_ADDR" "$ACL_IP_ADDR"
action 160 if $_string_result eq "1" goto 500
action 300 cli command "configure terminal"
action 310 cli command "ip access-list extended ACL_WAN_IN"
action 320 cli command "no 10"
action 330 cli command "10 permit object-group OBJGRP_PPS_IN any host
$CUR_IP_ADDR"
action 340 cli command "no 1000"
action 350 cli command "1000 deny ip any host $CUR_IP_ADDR log"
action 360 syslog priority warnings msg "ACL IP address changed from
$ACL_IP_ADDR to $CUR_IP_ADDR, please verify correct network operation."
action 490 exit 1
action 500 syslog priority informational msg "No change to DHCP IP address,
exiting."

```

We will run the script manually first to ensure it works. The current IP address on the WAN facing link is shown below. The script should take this IP and allow anything from the specified object-group (not shown) to enter the residential network.

```

R7#show ip interface brief | include 2.557
GigabitEthernet2.557    10.5.7.102      YES DHCP    up

```

There is an error in the script which can be revealed by using EEM debugging. This shows the input/output of commands and responses between EEM and the parser. The script is asking for an ACL called "WAN_IP" when the ACL is called "ACL_WAN_IP". The parser returns no output which is the same result one would see if the command were issued manually from the CLI. As such, the script cannot populate the variable I have defined, and the operations that rely on it will fail. This debugging is very useful to capture small typos (run-time errors) when writing EEM scripts.

```

R7#debug event-manager action cli
%HA_EM-6-LOG: UPDATE_WAN_IP : DEBUG(cli_lib) : : IN : R7#show ip access-list
WAN_IN | include OBJGRP
%HA_EM-6-LOG: UPDATE_WAN_IP : DEBUG(cli_lib) : : OUT : R7#
%HA_EM-3-FMPD_UNKNOWN_ENV: fh_parse_var: could not find environment variable:
ACL_IP_ADDR

```

The correction is easily made and is shown below. The benefit of having action "labels" is that it is easy to make changes to particular lines of code, much like sequence numbers in an ACL or route-map.

```

! CSR7
event manager applet UPDATE_WAN_IP
  no action 130 cli command "show ip access-list WAN_IN | include OBJGRP"
  action 130 cli command "show ip access-list ACL_WAN_IN | include OBJGRP"

```

The script only makes changes when the current IP address (on the interface) is different from the IP address inside the ACL. Assuming they are the same, nothing changes.

```

! CSR5
%HA_EM-6-LOG: UPDATE_WAN_IP : DEBUG(cli_lib) : : CTL : cli_open called.
%HA_EM-6-LOG: UPDATE_WAN_IP : DEBUG(cli_lib) : : OUT : R7>
%HA_EM-6-LOG: UPDATE_WAN_IP : DEBUG(cli_lib) : : IN : R7>enable
%HA_EM-6-LOG: UPDATE_WAN_IP : DEBUG(cli_lib) : : OUT : R7#
%HA_EM-6-LOG: UPDATE_WAN_IP : DEBUG(cli_lib) : : IN : R7#show ip interface
brief | include GigabitEthernet2.557
%HA_EM-6-LOG: UPDATE_WAN_IP : DEBUG(cli_lib) : : OUT : GigabitEthernet2.557
10.5.7.102 YES DHCP up up
%HA_EM-6-LOG: UPDATE_WAN_IP : DEBUG(cli_lib) : : OUT : R7#
%HA_EM-6-LOG: UPDATE_WAN_IP : DEBUG(cli_lib) : : IN : R7#show ip access-list
ACL_WAN_IN | include OBJGRP
%HA_EM-6-LOG: UPDATE_WAN_IP : DEBUG(cli_lib) : : OUT : 10 permit object-
group OBJGRP_PPS_IN any host 10.5.7.102 (42 matches)
%HA_EM-6-LOG: UPDATE_WAN_IP : DEBUG(cli_lib) : : OUT : R7#
%HA_EM-6-LOG: UPDATE_WAN_IP: No change to DHCP IP address, exiting.
%HA_EM-6-LOG: UPDATE_WAN_IP : DEBUG(cli_lib) : : CTL : cli_close called.

```

Assuming the two did not match, as shown below, the ACL gets updated with the current IP address. Rather than paste pages of debug, I only show the relevant parts.

```

! CSR7
%HA_EM-6-LOG: UPDATE_WAN_IP : DEBUG(cli_lib) : : IN : R7#show ip interface
brief | include GigabitEthernet2.557
%HA_EM-6-LOG: UPDATE_WAN_IP : DEBUG(cli_lib) : : OUT : GigabitEthernet2.557
10.5.7.102 YES DHCP up
%HA_EM-6-LOG: UPDATE_WAN_IP : DEBUG(cli_lib) : : IN : R7#show ip access-list
ACL_WAN_IN | include OBJGRP
%HA_EM-6-LOG: UPDATE_WAN_IP : DEBUG(cli_lib) : : OUT : 10 permit ip any
any (12 matches)

```

The script did not detect the string “10.5.7.102” inside a permit statement within the ACL. Now EEM will fix the ACL to match the DHCP address.

```

! CSR7
%HA_EM-6-LOG: UPDATE_WAN_IP : DEBUG(cli_lib) : : IN : R7#configure terminal
%HA_EM-6-LOG: UPDATE_WAN_IP : DEBUG(cli_lib) : : OUT : Enter configuration
commands, one per line. End with CNT
%HA_EM-6-LOG: UPDATE_WAN_IP : DEBUG(cli_lib) : : IN : R7(config)#ip access-
list extended ACL_WAN_IN
%HA_EM-6-LOG: UPDATE_WAN_IP : DEBUG(cli_lib) : : IN : R7(config-ext-nacl)#no
10
%HA_EM-6-LOG: UPDATE_WAN_IP : DEBUG(cli_lib) : : IN : R7(config-ext-nacl)#10
permit object-group OBJGRP_PPS_IN any host 10.5.7.102
%HA_EM-6-LOG: UPDATE_WAN_IP : DEBUG(cli_lib) : : IN : R7(config-ext-nacl)#no
1000

```

```
%HA_EM-6-LOG: UPDATE_WAN_IP : DEBUG(cli_lib) : : IN : R7(config-ext-
nacl)#1000 deny ip any host 10.5.7.102 log
%HA_EM-4-LOG: UPDATE_WAN_IP: ACL IP address changed from 1000 to 10.5.7.102,
please verify correct network operation.
```

We can verify the ACL was changed. Pinging from in->out should work, but telnet should not. A few basic tests confirm this.

```

```

We can synchronously automate this procedure by wrapping it with a cron timer script. This will run the script every day at 0600 and 1800. The cron timer works as follows: minute, hour, day, month, day of week. In this case, at 00 minutes, 06 and 18 hours, every day, every month, every day of the week, execute this action. Cron is a sizable Linux-oriented topic with many different options, but the basics are shown below. When this script runs, it will simply call the other script, as the main script has no associated event. Notice that actions are alphanumeric labels, not numbers, so they are sorted alphabetically ASCII-wise.

```
! CSR7
event manager applet SCHEDULER_WAN_IP
 event timer cron name CRON_TWICE_DAILY cron-entry "0 6,18 * * *"
 action 100 syslog priority informational msg "Starting routine IP check ..."
 action 110 cli command "enable"
 action 120 cli command "event manager run UPDATE_WAN_IP"
 action zzz syslog priority informational msg "Update complete."
```

I also added the following script to allow things to work when the DHCP server decides to assign a new address. This helps automate the process with an asynchronous check. The syslog messages are shown below, along with the ACL verification. Since the log messages contain their script names, it's easy to see which logs came from which scripts when you have nested policies. I use all ASCII labels to show that it is indeed sorted by ASCII decimal numbers (0-9, A-Z, a-z, not including special characters). In summary, this

script will invoke the UPDATE_WAN_IP script when DHCP issues a syslog indicating the WAN IP has changed. If, for some reason, that syslog does not appear, the timer-based script SCHEDULER_WAN_IP will run twice daily as a fail-safe.

```
! CSR7
event manager applet DHCPEVENT_WAN_IP
  event syslog occurs 1 pattern "assign.*DHCP.*address"
  action A syslog priority informational msg "DHCP indicates IP activity,
starting IP check ..."
  action Z cli command "enable"
  action a cli command "event manager run UPDATE_WAN_IP"
  action z syslog priority informational msg "Update complete."

%DHCP-6-ADDRESS_ASSIGN: Interface GigabitEthernet2.557 assigned DHCP address
10.5.7.104, mask 255.255.255.0, hostname R7
%HA_EM-6-LOG: DHCPEVENT_WAN_IP: DHCP indicates IP activity, starting IP check
...
%HA_EM-4-LOG: UPDATE_WAN_IP: ACL IP address changed from 2000 to 10.5.7.104,
please verify correct network operation.
%HA_EM-6-LOG: DHCPEVENT_WAN_IP: Update complete.

R7#show ip access-lists ACL_WAN_IN
Extended IP access list ACL_WAN_IN
  10 permit object-group OBJGRP_PPS_IN any host 10.5.7.104
  1000 deny ip any host 10.5.7.104 log
  2000 permit udp any any eq bootpc (2 matches)
```

A quick way to verify that user-written EEM scripts are registered (valid events, etc) is to query the EEM policy database. This shows the entire script, which can be long (omitted), but it's valuable to see the scripts in summary view.

```
R7#show event manager policy registered user
No.  Class    Type    Event Type    Trap    Time Registered    Name
1    applet    user    none          Off     DAY MON 20 23:26:26 2015  UPDATE_WAN_IP
  policyname {UPDATE_WAN_IP} sync {yes}
  maxrun 20.000
  action 100 cli command "enable"
[snip]

2    applet    user    timer cron    Off     DAY MON 20 23:27:24 2015  SCHEDULER_WAN_IP
  name {CRON_TWICE_DAILY} cron entry {0 6,18 * * *}
  maxrun 20.000
  action 100 syslog priority informational msg "Starting routine IP check ..."
[snip]

3    applet    user    syslog        Off     DAY MON 20 23:27:25 2015  DHCPEVENT_WAN_IP
  occurs 1 pattern {assign.*DHCP.*address}
  maxrun 20.000
```

```

    action A syslog priority informational msg "DHCP indicates IP activity, starting IP
check ..."
[snip]

```

Complex scripts like this can be very difficult to troubleshoot since there does not appear to be a way to show or debug commands to see the values of these locally-defined variables. For example, the logical comparisons and regexp operations are totally invisible to the user, it seems. Creating an environment (global scope) variable is visible, however. I believe that the variables used in the script are deallocated once the script completes, much like local variables in any procedural program language, so viewing them would be difficult. This is a side note and not relevant to the testing at hand. Example environment variables as shown below.

```

! CSR7
event manager environment ENV_VAR hello

R7#show event manager environment all
No.   Name                               Value
1     ENV_VAR                           hello

```

We can write a tiny script to display the value of this variable. This demonstrates the value of environment variables as they can be used to “pass” information between sequential scripts in lieu of true parameterization. One script could set the variable, another could manipulate it, and a third could display the results.

```

! CSR7
event manager applet SHOW_ENV_VAR
    event none
    action 010 puts "$ENV_VAR"

R7#event manager run SHOW_ENV_VAR
hello

```

44.4 Embedded Packet Capture (EPC)

EPC is a feature on IOS and XE routers that can capture packets entering or exiting between interfaces. It's a lightweight and no-frills tool, and the exported captures from EPC can be viewed as normal PCAP files on popular sniffer applications like Wireshark. This is valuable when trying to capture packets for inspection or troubleshooting. Because fancy tools like Wireshark are (likely) not available on CCIE lab exams, I prefer to use the hexadecimal buffer dumps to identify traffic. It works in both the CEF and process switching paths, unlike “debug ip packet”. EPC does come at a performance penalty, so use it sparingly. Up to this point, we have used EPC extensively for verification in the data-plane.

The most basic EPC policy matches all traffic and specifies a set of interfaces. For example, to measure all inbound traffic on CSR5 within the MPLS core, we can use this EPC. We verify it immediately after to ensure the filter (match any) and interfaces are correct. Because we have not started this capture, the

state is “Inactive”. There are no limits on the buffers length (bad idea in production) and no additional filters/samplers are applied.

```
! CSR5 (from exec mode)
monitor capture CORE match any
monitor capture CORE interface gig2.551 in
monitor capture CORE interface gig2.556 in
```

```
R5#show monitor capture CORE
Status Information for Capture CORE
```

Target Type:

Interface: GigabitEthernet2.551, Direction: in

Interface: GigabitEthernet2.556, Direction: in

Status : Inactive

Filter Details:

Capture all packets

Buffer Details:

Buffer Type: LINEAR (default)

Limit Details:

Number of Packets to capture: 0 (no limit)

Packet Capture duration: 0 (no limit)

Packet Size to capture: 0 (no limit)

Packet sampling rate: 0 (no sampling)

Similar to BGP dampening verification, we can also see the parameters of the EPC explicitly, to include defaults. These are the exact CLI commands, so you can copy/edit/paste as necessary. The buffer size of 10 is measured in MB, not packets. This is very handy for making quick modifications as you can copy/paste it into a text editor, make changes, and copy/paste the result directly into the CLI.

```
R5#show monitor capture CORE parameter
  monitor capture CORE interface GigabitEthernet2.551 in
  monitor capture CORE interface GigabitEthernet2.556 in
  monitor capture CORE match any
  monitor capture CORE buffer size 10
  monitor capture CORE limit pps 1000
```

We can start the capture, verify that it has started. This also creates a syslog message.

```
R5#monitor capture CORE start
%BUFCAP-6-ENABLE: Capture Point CORE enabled.
```

```
R5#show monitor capture CORE | include Status
Status Information for Capture CORE
  Status : Active
```

There are four ways to view the buffer, each showing varying levels of detail. The first is the summary view which talks about the buffer’s length, how many packets are in the buffer, at which rate do packets

enter the buffer, etc. No packet-level information is shown and this is only useful when trying to get a general idea of how much traffic is being captured by the filter.

```
R5#show monitor capture CORE buffer
buffer size (KB) : 10240
buffer used (KB) : 128
packets in buf   : 184
packets dropped  : 0
packets per sec  : 1
```

The next level of detail reveals a summary of all packet/frame headers. This is useful to troubleshoot basic reachability when layers of encapsulation/payloads are not relevant. It is especially valuable when the traffic is IPv4/v6 since those headers are clearly shown. Though MAC addresses are shown for non-IPv4/v6 Ethertypes, most administrators don't memorize MAC addresses on their network devices.

```
R5#show monitor capture CORE buffer brief
-----
#    size    timestamp      source                destination          protocol
-----
 0    82      0.000000      23.0.0.12             -> 23.0.0.5             ICMP
 1    80      0.048993      23.5.6.6               -> 224.0.0.2            UDP
 2    74      0.814005      23.5.6.6               -> 23.5.6.5             ICMP
 3    82      1.116998      23.0.0.12             -> 23.0.0.5             ICMP
 4    88      1.664018      23.5.11.11            -> 224.0.0.2            UDP
 5 1517      2.067989      00:50:56:A9:DE:0D     -> 09:00:2B:00:00:05    LLC
[snip]
```

Next, we can see additional detail of buffer entries. This is useful for seeing layers of encapsulation for the first 64 bytes of each packet; for IPv4, this is usually enough to see a few layers of encapsulation and the beginning of the payload. For IPv6, it may not be sufficient. As an example, I highlight the IP source/destination addresses in the first header as hexadecimal digits. The beginning of the packet's payload is shown in green; seeing this indicates that the entire packet encapsulation is visible and there is no need to progress to the next level of detail when trying to verify encapsulations.

```
R5#show monitor capture CORE buffer detail
-----
#    size    timestamp      source                destination          protocol
-----
 0    82      0.000000      23.0.0.12             -> 23.0.0.5             ICMP

 1    80      0.048993      23.5.6.6               -> 224.0.0.2            UDP
0000: 01005E00 00020050 56A9DE0D 81000DE4  ..^....PV.....
```

```

0010: 080045C0 003E0000 00000111 BBE21705 ..E..>.....
0020: 0606E000 00020286 0286002A C6290001 .....*)...
0030: 001E1700 00060000 01000014 00000000 .....

  2   74   0.814005   23.5.6.6       -> 23.5.6.5       ICMP
0000: 005056A9 DC630050 56A9DE0D 81000DE4 .PV..c.PV.....
0010: 080045C0 00383A1D 0000FF01 46D31705 ..E..8:.....F...
0020: 06061705 06050303 15840000 00004500 .....E.
0030: 00540382 0000FE11 85071705 06051700 .T.....

```

The most detailed view is the buffer dump. This is the raw hexadecimal information with no additional detail (no size calculations, timestamps, ASCII interpretation, etc). This is useful for troubleshooting large encapsulation stacks or payload (application) issues. Again, I highlight the IP source/destination addresses in the first packet. This command is only useful if you are comfortable reading hexadecimal, which I recommend for any CCIE lab exam.

```

R5#show monitor capture CORE buffer dump

[snip]

```

We can stop the buffer after we have collected the information we need. All of the aforementioned show commands can be used while the buffer is running or stopped.

```

R5#monitor capture CORE stop
%BUFCAP-6-DISABLE: Capture Point CORE disabled.

R5#show monitor capture CORE | include Status
Status Information for Capture CORE
  Status : Inactive

```

First, we will look at traffic filters. The simplest method is to apply them in-line with the policy. On CSR6, we will capture LDP messaging (transit or otherwise) arriving from XRv2 as long as it comes from within the SP address block. We will also limit the number of packets captured to 6. The buffer is linear, which means the 7th packet is not captured at all.

```

! CSR6 (in exec mode)
monitor capture CORE2 interface gig2.562 in match ipv4 protocol udp
23.0.0.0/8 any eq 646
monitor capture CORE2 limit packets 6

```

```

R6#show monitor capture CORE2
Status Information for Capture CORE2
  Target Type:
    Interface: GigabitEthernet2.562, Direction: in
    Status : Inactive
  Filter Details:
    IPv4
    Source IP: 23.0.0.0/8
    Destination IP: any
    Protocol: udp
    Destination port(s): = 646
  Buffer Details:
    Buffer Type: LINEAR (default)
  Limit Details:
    Number of Packets to capture: 6
    Packet Capture duration: 0 (no limit)
    Packet Size to capture: 0 (no limit)
    Packet sampling rate: 0 (no sampling)

```

We start the buffer and wait a few seconds for it to fill up with LDP messages. It doesn't take long with a buffer length of 6 packets.

```

R6#monitor capture CORE2 start
%BUFCAP-6-ENABLE: Capture Point CORE2 enabled.

```

The capture is automatically stopped when the packet count is reached. We can look at the buffer brief to see 6 LDP packets. In case there is any doubt that these are LDP packets, the buffer detail shows us some of the hexadecimal dump, and we can extract the UDP destination port 646 (0x286) from the messages.

```

! CSR5
%BUFCAP-6-DISABLE_ASYNC: Capture Point CORE2 disabled. Reason : Packet Count Reached

```

```

R6#show monitor capture CORE2 buffer brief
-----
#    size    timestamp      source                destination    protocol

We can also measure traffic destined specifically to the control-plane. We will measure BGP traffic in this way; CSR6 is potentially in the transit path for XRv2's BGP session to CSR5, so by capturing the control-plane only, the transit traffic is ignored. We will use the ACL for matching BGP traffic, versus an in-line filter, and set a time limit of 2 minutes (120 seconds). We can specify matching in "both" directions as well. You must configure the ACL before attaching it to EPC, as shown below.

```
! CSR6
monitor capture BGPCP control-plane both access-list ACL_BGP limit duration
120
```

Non-existent access-list specified
Failed to attach existing ACL

Assuming the ACL exists (matches TCP port 179), the binding is successful.

```
! CSR6
ip access-list extended ACL_BGP
 permit tcp any eq bgp any
 permit tcp any any eq bgp
```

```
monitor capture BGPCP control-plane both access-list ACL_BGP limit duration
120
```

```
R6#show monitor capture BGPCP
Status Information for Capture BGPCP
Target Type:
  Interface: Control Plane, Direction : both
  Status : Inactive
Filter Details:
  Access-list: ACL_BGP
Buffer Details:
  Buffer Type: LINEAR (default)
Limit Details:
  Number of Packets to capture: 0 (no limit)
  Packet Capture duration: 120
```

```
Packet Size to capture: 0 (no limit)
Packet sampling rate: 0 (no sampling)
```

```
R6#show access-list ACL_BGP
Extended IP access list ACL_BGP
 10 permit tcp any eq bgp any
 20 permit tcp any any eq bgp
```

We start the capture and it runs for 2 minutes. It automatically disables itself after that time period. The reason for the ~2.5 minute time difference is because the capture starts once the first packet is received, so it took about ~24 seconds for the first packet to be captured at time = 0.

```
! Time 18:43:26.385
R6#monitor capture BGPCP start
%BUFCAP-6-ENABLE: Capture Point BGPCP enabled.

! Time 18:45:50.504
%BUFCAP-6-DISABLE_ASYNC: Capture Point BGPCP disabled. Reason : Time Duration
Reached
```

The buffer brief shows 8 packets received over the capture period. We can see all of the traffic is between CSR6 and the RR (CSR5), with nothing else captured. Notice that the first packet in every capture is timestamped at time = 0. As mentioned above that capture does not start until the first matching packet is captured.

```
R6#show monitor capture BGPCP buffer brief
-----
#    size    timestamp      source          destination    protocol
-----
0    93      0.000000      23.0.0.6        -> 23.0.0.5      TCP
1    78      2.198039      23.0.0.5        -> 23.0.0.6      TCP
2    97      24.112985     23.0.0.5        -> 23.0.0.6      TCP
3    74      24.314030     23.0.0.6        -> 23.0.0.5      TCP
4    93      52.228036     23.0.0.6        -> 23.0.0.5      TCP
5    78      53.832009     23.0.0.5        -> 23.0.0.6      TCP
6   185      73.417022     23.0.0.5        -> 23.0.0.6      TCP
7    74      73.418029     23.0.0.6        -> 23.0.0.5      TCP
```

The detailed buffer information can show us the TCP port of 179 also. The TCP session table tells us that packets sent to CSR5 should have destination port 179 (0xB3) and source port 26511 (0x678F). We can confirm these ports are correct below by checking the TCP TCB for this particular BGP session.

```
R6#show tcp brief | include 179
7F4AA56B52E8  23.0.0.6.26511          23.0.0.5.179          ESTAB
```

```
R6#show monitor capture BGPCP buffer detailed
-----
```

#	size	timestamp	source	destination	protocol
0	93	0.000000	23.0.0.6	-> 23.0.0.5	TCP
0000:	00000000	00000000	00000000	080045C0	E.
0010:	004F0B2A	4000FF06	41B41700	00061700	.O.*@...A.....
0020:	0005678F	00B35AB2	075A23A5	3A7BA018	..g...Z...Z#..{..
0030:	3AC2784C	00001312	D0BF5878	101E6018	..xL.....Xx..`.

You can also use MQC class-maps to match traffic. NBAR is not currently supported, so I would consider this functionality limited when ACLs are available. DSCP matching also does not work. It could be useful as a way to test outbound QoS policies in advance, but right now the MQC support in EPC seems very limited. For this example, I configure a class-map to match large ping packets that arrive from CSR5. This combines a simple ACL with the packet length matching capability of the class-map. I also consider a packet per second (pps) limit which can conserve resources on the router. The circular buffer means that once the buffer is full (I reduced size to 2 MB), the oldest entries are overwritten by newer ones. This is unlike a linear buffer where new packets are rejected once the buffer is full as the capture stops automatically. Other examples of circular buffers include the XE syslog and Linux kernel ring buffers.

```
R6#show monitor capture BIGPING parameter
  monitor capture BIGPING interface GigabitEthernet2.556 in
  monitor capture BIGPING class-map CMAP_BIG_PING
  monitor capture BIGPING buffer size 2 circular
  monitor capture BIGPING limit pps 1000
```

```
! CSR6
ip access-list extended ACL_PING
  permit icmp any any echo

class-map match-all CMAP_BIG_PING
  match access-group name ACL_PING
  match packet length min 1000 max 1500
```

When we send packets less than 1000 bytes from CSR5 towards CSR6, they are not captured. These packets do not satisfy the minimum length condition of the class-map.

```
R5#ping 23.5.6.6 timeout 0 size 900
Type escape sequence to abort.
Sending 5, 900-byte ICMP Echos to 23.5.6.6, timeout is 0 seconds:
.....
```

```
R6#show monitor capture BIGPING buffer
buffer size (KB) : 2048
buffer used (KB) : 0
packets in buf   : 0
packets dropped  : 0
packets per sec  : 0
```

When we send packets that are greater or equal to 1000 bytes, or less than or equal to 1500 bytes ($1000 \leq x \leq 1500$), the packets are matched. The reason I tested this extensively was to prove that the limits of the match, 1000 and 1500, are inclusive. We sent exactly 15 packets across 3 pings and saw exactly 15 packets captured. The detailed output shows the different lengths as well.

```
R5#ping 23.5.6.6 timeout 0 size 1100
Type escape sequence to abort.

The last topic includes exporting these captures to remote file systems. This is commonly used to TFTP captured data to a management station for PCAP analysis (Wireshark, automated process, etc). Because I do not have a TFTP server, I will copy the file to bootflash as a .pcap file. We can read the file from memory directly (shown below) or save it offline until we set up a TFTP server later.

```
R6#monitor capture BIGPING export bootflash:bigping.pcap
Exported Successfully
```

```
R6#more bootflash:bigping.pcap
```

```

00000000: A1B2C3D4 00020004 00000000 00000000 !2CT .... ....
00000010: 00010000 00000001 55D8CD5E 000D9841 .... UXM^ ...A

```

Assuming we had a remote file system, the syntax is nearly identical, except we need to specify the server address. The process fails because I don't have a server online.

```

R6#monitor capture BIGPING export tftp://10.99.99.99/bigping.pcap
.....Failed to Export: Failed to create export file

```

Real XR routers with hardware linecards have some additional packet-capturing abilities, but XRv is limited. Using the “monitor interface” family of commands, we can see some real-time statistics. The command by itself displays the following screen. The screen updates every 2 seconds, and the user can use the commands listed at the bottom to control things. “Freeze” and “thaw” will stop and restart the refreshes, respectively. Most of the other commands are self-explanatory (quit, clear, etc). While this is running, we start a steady stream of pings from CSR5. We can see the increase in InBytes on Gig0/0/0/0.551 as a result. This counts against both the main and subinterfaces when this occurs.

```

RP/0/0/CPU0:XRv1#monitor interface
XRv1                      Monitor Time: 00:00:06                SysUptime: 411:29:22
Protocol:General
Interface                  In (bps)          Out (bps)          InBytes/Delta      OutBytes/Delta

We can also specify a specific interface to monitor for a more detailed view. With the ping from CSR5 still going, we examine Gig0/0/0/0.551. We can see the input/output rate of this ping flow is about 32 kbps at this point. Using the “i” command allows you to specify another interface without having to exit. There is no difference between the brief and detail views in XRv, either. The error statistics at the bottom would be particularly valuable when trying to assess how frequently those errors are occurring, and on which interfaces, in real time.

```
RP/0/0/CPU0:XRv1#monitor interface gig0/0/0/0.551
XRv1                               Monitor Time: 00:00:24           SysUptime: 411:34:58

45. Describe, implement, and troubleshoot port mirroring protocols

Because not all of these features are reasonably testable on all platforms, two labs are used. SPAN and RSPAN are tested using the TR-101 VLAN lab since it is a functional QinQ network with 3 Cisco ME-3400-24TS-A switches. ERSPAN will use a CSR1000v / XRv lab since we can avoid the complexities of hypervisor switches with IP-encapsulated sessions.

45.1 Switch port analyzer (SPAN)

SPAN (also called local SPAN) is a feature that allows a network device to capture traffic on a switch port and flood it out of another port for evaluation. This is very useful for troubleshooting when a packet

sniffer is attached to the “mirror” or “span” port. It also has security applications for intrusion detection systems (IDS). The feature can specify a number of source interfaces or VLANs along with a number of destinations interfaces (not VLANs). You also cannot mix port and VLAN sources in the same session. The configurations for this lab are rolled into the RSPAN session as well and are available at the end of the RSPAN session.

We will connect our sniffer to port 24 on ME2 (not shown in diagram) and simply “no shutdown” the port. The port-type does not matter when SPAN is used since the line-protocol is forced down. The switchport mode and VLANs also make no difference for a basic SPAN configuration. We will configure a basic SPAN session to look at bidirectional traffic on the backbone LACP bond to ME3 and mirror it to port 24.

```
! ME2
interface FastEthernet0/24
  description LOCAL SPAN
  no shutdown

monitor session 1 source interface Po1
monitor session 1 destination interface Fa0/24

ME2#show monitor session 1
Session 1
```

```

-----
Type                        : Local Session
Source Ports                :
    Both                    : Po1
Destination Ports          : Fa0/24
    Encapsulation           : Native
    Ingress                 : Disabled

```

We also verify that the port state is “monitoring”; this actually qualifies as line-protocol down.

```

ME2#show interfaces fastEthernet 0/24 status
Port      Name           Status      Vlan    Duplex  Speed Type
Fa0/24    LOCAL SPAN        monitoring  1       a-full  a-100 10/100BaseTX

```

We send some pings from ME3 to ME1 within VRF C1 (10.255.10.3 to 10.255.10.1). Below is a snapshot of what Wireshark sees. Notice that it captures the L2/L3 header with the proper C-MACs and C-IP addresses, but no VLAN encapsulation. Above, we see that the encapsulation is native, which means the original encapsulation is discarded by the SPAN process when replicating the traffic.

```

+ Frame 1: 114 bytes on wire (912 bits), 114 bytes captured (912 bits) on interface 0
+ Ethernet II, Src: CiscoInc_0b:16:c1 (00:1f:9d:0b:16:c1), Dst: CiscoInc_92:f7:41 (00:1d:46:92:f7:41)
+ Internet Protocol Version 4, Src: 10.255.10.3 (10.255.10.3), Dst: 10.255.10.1 (10.255.10.1)
+ Internet Control Message Protocol

```

To correct this, we can instruct SPAN to replicate the encapsulation towards the sniffer. I think there is a problem with the OS driver on my sniffer because it only shows the inner-most C-VLAN tag (value 10), when we know there is an S-tag on these frames as well. At a minimum, we see a difference in output which shows at some additional encapsulation, although ideally we would see all of it.

```

! ME2
monitor session 1 source interface Po1
monitor session 1 destination interface Fa0/24 encapsulation replicate

```

```

ME2#show monitor session 1
Session 1
-----
Type                        : Local Session
Source Ports                :
    Both                    : Po1
Destination Ports          : Fa0/24
    Encapsulation           : Replicate
    Ingress                 : Disabled

```

```

+ Frame 60: 118 bytes on wire (944 bits), 118 bytes captured (944 bits) on interface 0
+ Ethernet II, Src: CiscoInc_0b:16:c1 (00:1f:9d:0b:16:c1), Dst: CiscoInc_92:f7:41 (00:1d:46:92:f7:41)
+ 802.1Q Virtual LAN, PRI: 0, CFI: 0, ID: 10
+ Internet Protocol Version 4, Src: 10.255.10.3 (10.255.10.3), Dst: 10.255.10.1 (10.255.10.1)
+ Internet Control Message Protocol

```

We can also use the sniffer laptop like a regular host. Traffic coming from the sniffer can be placed into an “ingress” VLAN of our choice. I create a new VLAN 169 and apply a link-local IPv4 address to it. This will be in the same IP subnet as the NIC driver that is running Wireshark (169.254.0.1/24). In order to make the SVI go up, I have to add VLAN 169 to some port that is up, so I add it to the backbone LACP bond. This is clearly for testing purposes and generally you would have already have more ports in VLAN 169 if you were putting a host into that VLAN. We can specify the ingress replication as well in the event that the host was tagging traffic, but in this case, it is not.

```
! ME2
vlan 169
  name SPAN_INGRESS

interface Vlan169
  ip address 169.254.0.2 255.255.255.0

monitor session 1 source interface Po1
monitor session 1 destination interface Fa0/24 encapsulation replicate
ingress untagged vlan 169

interface Port-channel1
  switchport trunk allowed vlan add 169

ME2#show monitor session 1
Session 1
-----
Type                : Local Session
Source Ports        :
    Both            : Po1
Destination Ports   : Fa0/24
Encapsulation       : Replicate
    Ingress         : Enabled, default VLAN = 169
Ingress encaps      : Untagged
```

To test it, I will try to ping ME2’s SVI from the sniffer laptop. It appears to work, so I verify the ARP entry in the sniffer against the SVI MAC address to confirm.

```
C:\Users\Nick>ping 169.254.0.2
Pinging 169.254.0.2 with 32 bytes of data:
Request timed out.
Reply from 169.254.0.2: bytes=32 time=1ms TTL=255
Reply from 169.254.0.2: bytes=32 time=6ms TTL=255
Reply from 169.254.0.2: bytes=32 time=2ms TTL=255

Ping statistics for 169.254.0.2:
    Packets: Sent = 4, Received = 3, Lost = 1 (25% loss),
Approximate round trip times in milli-seconds:
```

Minimum = 1ms, Maximum = 6ms, Average = 3ms

```
C:\Users\Nick>arp -a
```

```
[snip]
```

```
Interface: 169.254.0.1 --- 0x6
```

Internet Address	Physical Address	Type
169.254.0.2	04-c5-a4-53-d8-41	dynamic

```
ME2#show interfaces vlan 169 | include bia
```

```
Hardware is EtherSVI, address is 04c5.a453.d841 (bia 04c5.a453.d841)
```

Last, we can specify which VLANs matter to us. When sniffing a trunk port, one may not want to see every VLAN, but rather an arbitrary subset. On ME2, we will capture on S-tagged traffic in VLAN 101 (which includes C1 and C2 but not C3) as well as VLANs 103 – 105. Since C3 traffic is inside VLAN 102, we should not see that traffic. The word “filter” uses positive logic and really means “match” as opposed to “remove”.

```
! ME2
```

```
monitor session 1 filter vlan 101 , 103 - 105
```

```
ME2#show monitor session 1
```

```
Session 1
```

```
-----
```

Type	: Local Session
Source Ports	:
Both	: Po1
Destination Ports	: Fa0/24
Encapsulation	: Replicate
Ingress	: Enabled, default VLAN = 169
Ingress encap	: Untagged
Filter VLANs	: 101,103-105

To test it, I send a single packet in each customer VRF across the network. The first two packets have an S-tag of 101 with C-tags of 10 and 20. The last packet has an S-tag of 102 with a C-tag of 30. All of this QinQ configuration was done in the TR-101 section.

```
ME3#ping vrf C1 10.255.10.1 repeat 1
```

```
Type escape sequence to abort.
```

```
Sending 1, 100-byte ICMP Echos to 10.255.10.1, timeout is 2 seconds:
```

```
!
```

```
Success rate is 100 percent (1/1), round-trip min/avg/max = 8/8/8 ms
```

```
ME3#ping vrf C2 10.255.20.1 repeat 1
```

```
Type escape sequence to abort.
```

```
Sending 1, 100-byte ICMP Echos to 10.255.20.1, timeout is 2 seconds:
```

```
!
```

```
Success rate is 100 percent (1/1), round-trip min/avg/max = 8/8/8 ms
```

```
ME3#ping vrf C3 10.255.30.1 repeat 1
Type escape sequence to abort.
Sending 1, 100-byte ICMP Echos to 10.255.30.1, timeout is 2 seconds:
!
Success rate is 100 percent (1/1), round-trip min/avg/max = 8/8/8 ms
```

I also adjust my Wireshark columns to display the VLAN ID in the summary view rather than the length. For some reason, Wireshark won't update the column header, but that column outlined in red represents the VLAN ID. Again, despite us matching on VLAN 101, we can only see the C-tags due to a driver issue (probably). At least this confirms that VLAN 101 is actually being used, otherwise the SPAN configuration would be invalid. Trying to match C-tags on that backbone LACP bond, would example, would yield unexpected/undesirable results. In this case, it would yield no results since VLANs 10, 20, and 30 are not used in the provider network at all. Of greatest importance is that traffic to 10.255.30.1 was not captured since the S-tag was 102, which was not candidate for SPAN treatment on ME2.

No.	Time	Source	Destination	Protocol	Length	Info
10	178.544803000	10.255.10.3	10.255.10.1	ICMP	10	Echo (ping) request
10	178.545638000	10.255.10.1	10.255.10.3	ICMP	10	Echo (ping) reply
20	179.986309000	10.255.20.3	10.255.20.1	ICMP	20	Echo (ping) request
20	179.987776000	10.255.20.1	10.255.20.3	ICMP	20	Echo (ping) reply

45.2 Remote SPAN (RSPAN)

RSPAN is very similar to SPAN but adds one capability; the ability to have the SPAN destination be a VLAN. Local SPAN can read traffic from VLANs or ports, but only mirror it to local interfaces. RSPAN can read from VLANs or ports as well, but flood the traffic into a specially-defined RSPAN VLAN. These VLANs still participate in STP and exist in the VLAN database, but have MAC address learning disabled. This makes sense considering the traffic is being forced into a VLAN with destination MAC addresses that don't exist in that VLAN normally.

Continuing from the SPAN lab, we have a Wireshark sniffer plugged into port 24 on ME2. SPAN and RSPAN can coexist, and we will prove it by not removing the SPAN session we configured earlier. The second monitor session will be an RSPAN session, and this ME platform only supports a maximum of 2 sessions. If you try to configure more, the parser prevents it.

```
ME2(config)#monitor session 3 source interface fast0/5
% Platform can support a maximum of 2 source sessions
```

First, we need to define the RSPAN VLANs. We can define as many as we wish, and these VLANs must be transportable across the network between the source and destination. Specifically, we will capture traffic coming from C3 on ME3, put it into an RSPAN VLAN, send it to ME2, and mirror it to our sniffer connected to port 24. Since VLANs 101 – 109 are already defined and allowed on the backbone LACP bond, I will define VLANs 108 and 109 as RSPAN VLANs. We only need one for this test, but I demonstrate that multiple RSPAN VLANs can exist, which is valuable when there are multiple different

remote captures is happening concurrently between different sets of switches. I add names for these VLANs for clarity, but it isn't required. The "remote-span" option is required for these VLANs to operate as RSPAN VLANs; this is the keyword that effectively disables MAC address learning for these VLANs.

```
! ME2 and ME3
vlan 108
  name RSPAN_PRIMARY
  remote-span

vlan 109
  name RSPAN_ALTERNATE
  remote-span
```

Don't be fooled by the MAC address learning show command; this command represents what is explicitly configured with the "mac address-table learning" command. The RSPAN VLANs do actually have MAC learning disabled, so don't use this command to verify as it is misleading.

```
ME2#show mac address-table learning vlan 108
VLAN      Learning Status
----      -
108       yes
```

```
ME2#show mac address-table learning vlan 109
VLAN      Learning Status
----      -
109       yes
```

RSPAN is configured on both the source and destination ends. The source (where traffic is captured) will read from a port or VLAN and mirror traffic into a VLAN. Port 22 is ME3's link to the "customer" switch C3 (really a jumper) and is a dot1q-tunnel port. We can perform captures on this port on ingress only, as an example. I also capture outbound-only on the LACP bond to ME2. In this way, we should see the same packet twice in Wireshark, and ideally with different VLAN encapsulations (incoming on port 22, outgoing on port-channel 1). The traffic is sent into RSPAN VLAN 108, which means 109 is unused.

```
! ME3
monitor session 2 source interface Fa0/22 rx
monitor session 2 source interface Po1 tx
monitor session 2 destination remote vlan 108

ME3#show monitor session 2
Session 2
-----
Type                               : Remote Source Session
Source Ports                       :
  RX Only                         : Fa0/22
  TX Only                         : Po1
```

```
Dest RSPAN VLAN : 108
```

ME2 has to receive traffic from the RSPAN VLAN and copy it to a destination port. Since two monitor sessions cannot share a destination port, we will move the cable from port 24 to port 23 on ME2.

```
ME2(config)#monitor session 2 destination interface fastEthernet 0/24
% Interface(s) Fa0/24 already configured as monitor destinations in other
monsessions
```

The port configuration is very simple and is shown below. I configure encapsulation replicate although it doesn't help us at all. This is the biggest downside of RSPAN; since traffic is carried inside an RSPAN VLAN, the originate encapsulation is always lost.

```
! ME2
interface FastEthernet0/23
  description LOCAL SPAN
  no shutdown

monitor session 2 source remote vlan 108
monitor session 2 destination interface Fa0/23 encapsulation replicate
```

We will send one packet in each customer VRF from ME3 to ME1 as a test. The results are successful but are omitted for brevity.

```
ME3#ping vrf C1 10.255.10.1 repeat 1
ME3#ping vrf C2 10.255.20.1 repeat 1
ME3#ping vrf C3 10.255.30.1 repeat 1
```

Despite having captured on ingress from the customer and egress to the AN on ME3, we see no encapsulation at all. The "length" column is really the VLAN tag, and being blank, there are no tags on these packets. We sent 3 packets yet see four entries. The first two were captured outbound on the LACP bond to ME2. The third packet is shown twice because it was captured once on ingress from C3 and again on egress on the LACP bond. There are no replies captured for any ping because traffic is only being captured in one general direction (ME3 to ME1).

No.	Time	Source	Destination	Protocol	Length	Info
	0.000000000	10.255.10.3	10.255.10.1	ICMP		Echo (ping) request
	5.081038000	10.255.20.3	10.255.20.1	ICMP		Echo (ping) request
	9.248830000	10.255.30.3	10.255.30.1	ICMP		Echo (ping) request
	9.248885000	10.255.30.3	10.255.30.1	ICMP		Echo (ping) request

We quickly check ME2 and ME3 CAM tables to ensure there are no MAC addresses learned in VLAN 108. It is not well-known that this is a workaround for disabling MAC learning in a VLAN in general. On a switch that may not support the "mac address-table learning" command, defining a VLAN as RSPAN will

have a similar effect. This might be useful for EPL or EVPL services where learning all of the MAC addresses across a P2P Ethernet circuit is inefficient for the carrier's switches.

```
ME2#show mac address-table dynamic vlan 108
      Mac Address Table
```

```
-----
Vlan    Mac Address      Type      Ports
----    -
[no output]
```

```
ME3#show mac address-table dynamic vlan 108
      Mac Address Table
```

```
-----
Vlan    Mac Address      Type      Ports
----    -
[no output]
```

Additional Reading – Reference configurations "span-rspan"

45.3 Encapsulated RSPAN (ERSPAN)

ERSPAN is meant to behave just like RSPAN except is used when the mirrored traffic must be transported over a layer 3 network. In RSPAN, we identified special RSPAN VLANs with MAC learning disabled so that those VLANs could transport mirrored traffic across a switched network. ERSPAN performs a similar concept but uses GRE encapsulation to transport mirrored traffic over IPv4. Since the feature is newer than SPAN/RSPAN, it is not available in the ME3400 platforms, so I use an existing, large-scale CSR1000v/XRv network to demonstrate it.

This lab is based on the MPLS IP/MTU minor features from earlier. The diagram is the same but there are some minor changes with the configuration. Familiarize yourself with this network topology by first reading the aforementioned chapter. The existing network is very involved with many advanced features configured.

We will pretend that CSR10 has a sniffer host connected to its Gig3 port, but this is unnecessary since we just connect CSR9's Gig3 to a bogus port-group in ESXi, then use outbound EPC locally on CSR9 to see

mirrored traffic. For capturing traffic responsibly, I delete CSR7's Gig2.567 interface and use Gig3 instead. This is plugged into an access-port (untagged port-group) on the same vSwitch as the general-purpose trunk on VLAN 3567. Thus, CSR6 and CSR7 have reachability over this link, but CSR7 uses a dedicated "physical" interface. Below is a quick snapshot of the IS-IS neighbors on CSR7, and we can see CSR6 is reachable via Gig3. The configuration is not shown as it is identical to the Gig2.567 configuration from the MPLS IP/MTU lab.

```
R7#show isis neighbors
```

```
Tag 211:
```

System Id	Type	Interface	IP Address	State	Holdtime	Circuit Id
R6	L2	Gi3	211.6.7.6	UP	26	01
R8	L2	Gi2.578	211.7.8.8	UP	9	R8.02
XRv1	L2	Gi2.571	211.7.11.11	UP	21	00
XRv2	L2	Gi2.572	211.7.12.12	UP	25	00
XRv3	L2	Gi2.578	211.7.8.13	UP	21	R8.02

On CSR9, all we need to do is no-shutdown the port. I add a description for clarity; this simple configuration is similar to SPAN and RSPAN where the destination port doesn't require anything fancy.

```
! CSR9
interface GigabitEthernet3
  description ERSPAN DESTINATION TEST PORT
  no shutdown
```

Just like with RSPAN, we must configure the source and destination. An ERSPAN source is the point where traffic is captured, and the destination is where it is sent (destination terminates a session). We will configure the destination first since it is less involved. We define the ERSPAN session and specify the proper type. We can select a set of destination interfaces as well; in this case, the test port is used. Each ERSPAN session as a session ID to demultiplex the ERSPAN sessions when one device has multiple sessions configured between the same set of IP addresses. The IP address on the destination session is the tunnel destination; that is, it is on this IP address that the router expects to receive ERSPAN-mirrored traffic. Sessions require "no-shutdown" as well.

```
! CSR9
monitor session 1 type erspan-destination
  no shutdown
  description LINK-BETWEEN-CSR6-AND-CSR7
  destination interface Gi3
  source
    erspan-id 1023
    ip address 211.0.0.9
```

The show command for this basically just echoes the configuration details. We can verify that everything is correct; also, note the MTU as we will be verifying this later. ERSPAN is accounting for 36 bytes of encapsulation.

```
R9#show monitor session 1
```

```
Session 1
```

```
-----
```

```
Type : ERSPAN Destination Session
Status : Admin Enabled
Description : LINK-BETWEEN-CSR6-AND-CSR7
Destination Ports : Gi3
Source IP Address : 211.0.0.9
Source ERSPAN ID : 1023
MTU : 1464
```

The ERSPAN source configuration looks and feels like a GRE tunnel. We configure the origin IP address (source) and the session IP address (destination). The ERSPAN ID has to match as well, and we can optionally specify the session VRF, TTL, and DSCP values. These options are equivalent to the features normally available on a GRE tunnel interface. I adjust some of these parameters for variety. The source interface is Gig3, which is connected to CSR6.

```
! CSR7
description CSR6-CSR7-TO-CSR9
source interface Gi3
destination
  erspan-id 1023
  ip address 211.0.0.9
  ip dscp 16
  ip ttl 8
  origin ip address 211.0.0.7
```

Because the ERSPAN source is more involved, we can verify it with the detail command. Towards the bottom, we can verify our minor options with this command. The MTU is computed at 1464 as well.

```
R7#show monitor session 1 detail
```

```
Session 1
```

```
-----
```

```
Type : ERSPAN Source Session

IP TTL           : 8

```

Looking at CSR9's capture, we can see a lot of information, even within the first few seconds of the capture. All of the traffic is source from either CSR6 or CSR7 on the link we are capturing. CSR9 is receiving the GRE packets, de-encapsulating the traffic, and sending it out of port Gig3. Most of this idle traffic is likely IS-IS, LDP, and possibly BGP.

```
R9#show monitor capture CAP buffer brief
```

#	size	timestamp	source	destination	protocol
0	93	0.000000	211.0.0.6	-> 211.0.0.7	TCP
1	74	0.200978	211.0.0.7	-> 211.0.0.6	TCP
2	104	0.380977	00:50:56:A9:DE:0D	-> 09:00:2B:00:00:05	LLC
3	76	1.275987	211.6.7.7	-> 224.0.0.2	UDP
4	93	1.605016	211.0.0.7	-> 211.0.0.6	TCP
5	76	1.805003	211.6.7.6	-> 224.0.0.2	UDP
6	74	1.807002	211.0.0.6	-> 211.0.0.7	TCP
7	60	2.652011	00:50:56:A9:25:E6	-> 09:00:2B:00:00:04	LLC
8	72	4.695008	211.0.0.7	-> 211.0.0.6	TCP

CSR7 has three EMCP paths to reach 211.0.0.9 which is the tunnel destination. According to the parser, traffic should be sent to CSR8 using label 8016.

```
R7#show ip cef 211.0.0.9/32
```

```
211.0.0.9/32
```

```

  nexthop 211.7.8.8 GigabitEthernet2.578 label 8016
  nexthop 211.7.8.13 GigabitEthernet2.578 label 93002
  nexthop 211.7.12.12 GigabitEthernet2.572 label 92004

```

```
R7#show ip cef exact-route 211.0.0.7 211.0.0.9
```

```

211.0.0.7 -> 211.0.0.9 => label 8016 TAG adj out of GigabitEthernet2.578, addr
211.7.8.8

```

However, a quick EPC outbound on CSR7 reveals that traffic is being sent to XRv3. This is interesting as I have no explanation as to why this would happen. If CSR7 is encapsulating traffic locally from 211.0.0.7 to 211.0.0.9 and not consulting the FIB, I am not sure what table it is consulting. Nonetheless, we can examine the EPC below, and we know it is going to XRv3 due to the destination MAC address and label value of 93002 (yellow). The IP header has TOS 64, which is DSCP 16 in cyan. The TTL is 8 and the IP protocol is 47 (pink). In green are the tunnel source and destination addresses, which are 211.0.0.7 and 211.0.0.9, respectively. A new packet type has been identified for ERSPAN, and it is 0x88BE (yellow shows the entire GRE header) Also notice that sequence numbers are enabled for the ERSPAN session per the 0x1 flag in the GRE header (this is why the GRE header is 8 bytes). Since GRE has to specify what it is carrying, this new field is important. Inside the ERSPAN payload, some additional information is carried, such as the ERSPAN ID of 1023 (grey). Later, the captured layer 2 frame is shown; in this case, the destination MAC address is highlighted in cyan and this was probably an LDP hello with destination IP address 224.0.0.2. We can tell this based on the MAC address.

```
R7#show ip arp 211.7.8.13
Protocol  Address          Age (min)  Hardware Addr  Type   Interface
Internet  211.7.8.13       220       0050.56a9.ea54  ARPA   Gig2.578

R7#show monitor cap CAP buffer detailed
 0  134      0.000000  00:50:56:A9:EA:77 -> 00:50:56:A9:EA:54 MPLS unicast
0000:  005056A9 EA540050 56A9EA77 81000DFA .PV..T.PV..w....
0010:  884716B4 A5084540 00700000 4000082F .G....E@.p..@../
0020:  CC0ED300 0007D300 00091000 88BE0000 .....
0030:  4C111001 03FF0000 00000100 5E000002 L.....^....
```

There isn't much more to ERSPAN than this. The packet breakdown shown above is pretty self-explanatory, though I admit I guessed the ERSPAN-ID would have been the GRE tunnel key. Instead, ERSPAN adds 8-bytes of additional overhead to carry important session information used by the ERSPAN process. Now, we can see why MTU 1464 makes sense: 1500 – 20 IP – 8 GRE – 8 ERSPAN = 1464 bytes.

46. Describe, implement, and troubleshoot Netflow and IPFIX

FNF is the successor to ordinary Netflow that is used primarily to measure, aggregate, and export traffic in the network. It can be used for security, billing, capacity planning, or general network management purposes. I personally use it often for troubleshooting; you can apply it quickly to an interface and see the fields of your choice. It is similar to EPC in this way, except it is part of the configuration and thus is more permanent. FNF is broken into three main components:

- a. **Record:** This determines what is being matched, somewhat like a class-map in MQC. Individual fields are specified here that comprise the entry. Fields can be identified as “key” (“match” command) or “nonkey” (“collect” command). The difference is that key fields are attributes that identify a flow; if two packets arrive on a router and all N of the key fields are identical, the two

packets are part of the same flow. If any key field differs, the packets are considered different flows. Nonkey fields are allowed to be different within the same flow. For example, a telnet session from A to B will likely have the same IP protocol, TOS, source/destination IP addresses and ports for its journey. Even if these packets are received by remote routers in different input interfaces (which are often nonkey), the traffic is considered one flow. Receiving traffic on different interfaces might be due to load-sharing schemes in the network core. A different source port, for example, would probably indicate a new telnet connection between the same set of hosts, which is legitimately a separate flow.

- b. **Exporter:** Defines the mechanism by which FNF records are sent to a collector. This includes source/destination IP address and port information, Netflow version, and other parameters that should match what the collector is expecting.
- c. **Monitor:** The monitor object contains a record (required) and an exporter (optional). The monitor also specifies the size of the cache and various timeout values. Two important timeout values are the “inactive” and “active” timers. Inactive starts counting from the moment a flow stops being seen by the device; this is the moment that the flow is considered inactive. The flow is purged from the cache after this timeout expires. The active timer is the maximum length of time a single flow is kept in the cache. If the length of the flow exceeds this time, the record is exported and purged, and then a new record starts to capture all packets after the active timer’s expiration. There are different cache types also, most of which are self-explanatory, that determine when flows are purged from the cache.

One critical change in v9 that is different from v5 is that it is template-based. Users do not modify templates directly, but templates are created based off of the information the user wishes to export. For example, a record may match 4 fields. Those fields may be variable in length; IPv4 addresses are 4 bytes, IPv6 addresses are 16, VLAN IDs are 2 (not counting the 0x8100 ethertype), etc. The exporter assembles all this information into a template so that records received from the exporter are intelligible and arranged in a deterministic fashion. Every template has an ID which is used internally to the Netflow process to identify a template.

The network diagram is shown below and is very similar to the alarm/capture test. CSR9 is an OOBM host used for Netflow collection while the majority of the Netflow configuration will be done on CSR5.

Note: Netflow does not appear to be supported at all in XRv versions 5.3.0 or 5.3.1.

```
RP/0/0/CPU0:XRv1(config)#flow?
flowspec
```

Additional Reading – Reference configurations "netflow"

46.1 Flexible Netflow (FNF)

FNF is supported on a per-interface basis for IPv4, IPv6, and MPLS traffic. First, we will create a basic IPv4 policy with all key fields on CSR5. This will capture the specified information from each IPv4 packet received from CSR7.

```
! CSR5
flow record FLOW_RECORD_IPV4
 match ipv4 dscp
 match ipv4 protocol
 match ipv4 source address
 match ipv4 destination address
 match transport source-port
 match transport destination-port
 match interface input
```

For now, we will not configure an exporter. Wrapping this record inside a monitor is the next step. We will tune the active/inactive timers as well as the cache size for variety. Using an inactive timer of 60 seconds gives us more time to see flows in the cache before they are quickly removed; this is very useful for troubleshooting.

```
! CSR5
flow monitor FLOW_MONITOR_IPV4
 cache timeout inactive 60
```

```
cache timeout active 300
cache entries 2048
record FLOW_RECORD_IPV4
```

The third and final step is to apply this to the interface facing CSR7. You can use this to specify unicast or multicast as well, plus apply any samplers (discussed later). At present, we see no records in the cache.

```
! CSR5
interface GigabitEthernet2.557
 ip flow monitor FLOW_MONITOR_IPV4 input
```

```
R5#show flow monitor FLOW_MONITOR_IPV4 cache
Cache type:                Normal (Platform cache)
Cache size:                2048
Current entries:           0
Flows added:               0
Flows aged:               0
```

There are no cache entries to display.

Now, we will send some ping/telnet traffic from CSR5 to XRv4 (not shown). The inactive timer gives us 60 seconds from the time the flow ends before it is purged from the cache, giving me time to view the results. The default is only 15 seconds which makes FNF less valuable for troubleshooting unless you tune it. There are three formats in which to view the information: record, table, and CSV. “Record” prints each field line-by-line, which is the most verbose. “Table” prints them arrayed horizontally with each row being an entry, which is my personal favorite. Beware that if you have many fields (more than ~6), table is a poor choice since it will wrap around the terminal screen. “CSV” is the least verbose and is good for pasting into a spreadsheet that understands CSV lists. All three versions are shown below; “Record” is the default and is shown first.

```
R5#show flow monitor FLOW_MONITOR_IPV4 cache
Cache type:                Normal (Platform cache)
Cache size:                2048
Current entries:           2
High Watermark:           2

Flows added:               2
Flows aged:               0
```

```
IPV4 SOURCE ADDRESS:      10.5.7.105
IPV4 DESTINATION ADDRESS: 10.14.14.14
TRNS SOURCE PORT:         0
TRNS DESTINATION PORT:    2048
INTERFACE INPUT:          Gi2.557
IP DSCP:                   0x00
IP PROTOCOL:              1
```

```

IPV4 SOURCE ADDRESS:      10.5.7.105
IPV4 DESTINATION ADDRESS: 10.14.14.14
TRNS SOURCE PORT:         4096
TRNS DESTINATION PORT:    23
INTERFACE INPUT:          Gi2.557
IP DSCP:                  0x30
IP PROTOCOL:              6

```

```

R5#show flow monitor FLOW_MONITOR_IPV4 cache format table
[snip]

```

IPV4 SRC ADDR	IPV4 DST ADDR	TRNS SRC PORT	TRNS DST PORT	INTF INPUT	IP DSCP	IP PROT
10.5.7.105	10.14.14.14	0	2048	Gi2.557	0x00	1
10.5.7.105	10.14.14.14	4096	23	Gi2.557	0x30	6

```

R5#show flow monitor FLOW_MONITOR_IPV4 cache format csv
[snip]

```

```

IPV4 SRC ADDR,IPV4 DST ADDR,TRNS SRC PORT,TRNS DST PORT,INTF INPUT,IP DSCP,IP PROT
10.5.7.105,10.14.14.14,0,2048,Gi2.557,0x00,1
10.5.7.105,10.14.14.14,4096,23,Gi2.557,0x30,6

```

If we come back a few minutes later, we can see both flows are gone due to aging. The cache shows 2 aged flows and the reason why.

```

R5#show flow monitor FLOW_MONITOR_IPV4 cache
Cache type:                      Normal (Platform cache)
Cache size:                      2048
Current entries:                 0
High Watermark:                 2

Flows added:                    2
Flows aged:                     2
- Inactive timeout ( 60 secs)  2

```

There are no cache entries to display.

Next, we will configure IPv6 FNF. It is identical to IPv4 except we can include IPv6 specific fields like flow-label if we choose. I will introduce the FNF exporter here. We will create a policy to account for the IPv6 flow label (key), and some layer 2 information as well (nonkey). We can use the layer 2 matches for IPv4, IPv6, or MPLS. Because it is a lower OSI layer, the data-link fields apply to any layer 3 protocol. We will remove the IPv6 DSCP and IP protocol matches for variety.

```

! CSR5
flow record FLOW_RECORD_IPV6
match ipv6 flow-label
match ipv6 source address
match ipv6 destination address
match transport source-port
match transport destination-port

```

```

match interface input
collect datalink source-vlan-id
collect datalink mac source address input

```

We will create an exporter to send these IPv6 records we collect to the FNF collector, CSR9. I can specify the TOS and TTL of these export messages also; I increase the TOS to CS6 and decrease the TTL to 1 since CSR9 is one hop away. This TTL adjustment is for security reasons. The destination is in the MGMT VRF and I can explicitly specify a source, although in this case it doesn't matter. The "option vrf-table" command allows FNF to capture the VRF table information from which the packets were received, which is VRF SHR. This could be useful in an SP environment on a PE router. By default, FNFv9 is used with UDP port 9995. I will name this exporter with a string containing "COMMON" because I can reuse it for other monitors; chances are you don't have a different collector for each traffic type (IPv4, IPv6, and MPLS).

```

! CSR5
flow exporter FLOW_EXPORTER_COMMON_V9
 destination 10.31.5.209 vrf MGMT
 source GigabitEthernet1
 dscp 48
 ttl 1
 option vrf-table

```

We can verify the configuration of the exporter using the command below. All of this is information that can be configured under the exporter, and seeing it this way also reveals the defaults. The least common known thing about FNF is the default transport is UDP 9995; ensure any data-plane filters permit UDP 9995 from network devices to the FNF collector.

```

R5#show flow exporter FLOW_EXPORTER_COMMON_V9
Flow Exporter FLOW_EXPORTER_COMMON_V9:
  Description:                User defined
  Export protocol:             NetFlow Version 9
  Transport Configuration:
    Destination IP address:    10.31.5.209
    VRF label:                 MGMT
    Source IP address:         10.31.5.205
    Source Interface:          GigabitEthernet1
    Transport Protocol:        UDP
    Destination Port:          9995
    Source Port:               54907
    DSCP:                      0x30
    TTL:                       1
    Output Features:           Used
  Options Configuration:
    vrf-table (timeout 600 seconds)

```

The monitor for IPv6 is slightly different. We use the IPv6 record with the COMMON exporter defined above, where IPv4 does not have an exporter currently. We will set the cache type to permanent which

means entries are never purged, so tuning the timers is not necessary. We also apply this as an IPv6 flow monitor to the interface facing CSR7. The monitor also specifies that only unicast traffic is candidate for capture, which is good on links where IGP is running (don't need to capture LL multicast, etc). Currently there is nothing in the cache.

```
! CSR5
flow monitor FLOW_MONITOR_IPV6
  exporter FLOW_EXPORTER_COMMON_V9
  cache type permanent
  record FLOW_RECORD_IPV6

! CSR5
interface GigabitEthernet2.557
  ipv6 flow monitor FLOW_MONITOR_IPV6 unicast input
```

```
R5#show flow monitor FLOW_MONITOR_IPV6 cache
Cache type: Permanent (Platform cache)
Cache size: 200000
Current entries: 0

Flows added: 0
Updates sent ( 1800 secs) 0
```

There are no cache entries to display.

Next, CSR7 will send ping/telnet traffic to XRv14 again using IPv6 addresses (not shown). In order to make it readable, I will use the record format, although table/CSV are also valid. Because we are no longer capturing DSCP or IP protocol, these flows almost look the same. The only differentiator at this point is source/destination port. Also notice that the data-link fields are in lower-case while all other fields are in upper-case; this denotes nonkey versus key fields.

```
R5#show flow monitor FLOW_MONITOR_IPV6 cache format record
Cache type: Permanent (Platform cache)
Cache size: 200000
Current entries: 0

Flows added: 0
Updates sent ( 1800 secs) 0

INTERFACE INPUT:                Gi2.557
layer 2 source vlan id:         3557
datalink mac source address input: 0050.56A9.EA77

```

These entries will never age out. Over time, the IPv6 ND packets will enter the cache also. Presently, there are 6 flows in the cache. I show them in CSV format below just you can count the 6 rows.

```

R5#show flow monitor FLOW_MONITOR_IPV6 cache format csv
IPV6 FLOW LABEL,IPV6 SRC ADDR,IPV6 DST ADDR,TRNS SRC PORT,TRNS DST PORT,INTF
INPUT,l2 src vlan id,datalink mac src addr input

0,FE80::7,FE80::5,0,34816,Gi2.557,3557,0050.56A9.EA77

```

We can manually clear any cache, regardless of type, using manual commands. When this occurs, the records are consolidated into UDP 9995 packets and sent to the collector. The “timeout update” parameter under the flow monitor controls this export interval, which is 30 minutes (1800 seconds) by default.

```
R5#clear flow monitor FLOW_MONITOR_IPV6 cache
```

```

R5#show flow monitor FLOW_MONITOR_IPV6 cache
Cache type:                Permanent (Platform cache)
Cache size:                200000
Current entries:           6
High Watermark:           6
Flows added:              6
Updates sent                ( 1800 secs) 0

```

```
There are no cache entries to display.
```

We can see the statistics of packets (4) and records (6) sent to the collector. Records are typically sent to the collector when they expire, but in permanent caches, that never happens. This has a separate timer because the information still remains in the FNF device, but the collector just receives updates, not purged records.

```
R5#show flow exporter FLOW_EXPORTER_COMMON_V9 statistics
```

```

Flow Exporter FLOW_EXPORTER_COMMON_V9:
  Packet send statistics (last cleared 00:16:10 ago):
    Successfully sent: 4 (622 bytes)

Client send statistics:
  Client: Option options vrf-id-name-table
    Records added: 6
    - sent: 6
    Bytes added: 216
    - sent: 216

  Client: Flow Monitor FLOW_MONITOR_IPV6
    Records added: 0
    Bytes added: 0

```

Last, we will examine MPLS FNF. The general logic is the same, except we won't be matching IPv4/v6 headers inside the FNF record, we will be matching MPLS label information. You can match up to 6 labels deep, but in our architecture, even with TE-FRR, we would have a maximum of 3. The labels in the stack will be the key fields, and I will collect packet and byte counts as nonkey fields. This means that we can see how many packets/bytes are identified with each flow.

```

! CSR5
flow record FLOW_RECORD_MPLS
  match mpls label 1 details
  match mpls label 2 details
  match mpls label 3 details
  collect counter bytes
  collect counter packets

```

There are two types of caches we have not tested yet. The "immediate" type ages out entries as soon as they are seen; for our purposes, this would not be helpful since we don't have a FNF collector where we can see the information. All other timers do not apply when using this mode. We will use the new "synchronized" cache type for our MPLS packets. This feature was specifically introduced to protect against "export storms". The synchronized interval is basically a timer that exports records when the timer expires, but in large caches, we may want to spread those exports over time to as not to storm the Netflow collector (NFC). This is especially true in networks where many devices are synchronized to export records at the same time. We will configure a 30 second interval with spreading over the first 10 seconds of the next interval.

```

! CSR5
flow monitor FLOW_MONITOR_MPLS
  exporter FLOW_EXPORTER_COMMON_V9
  cache timeout synchronized 30 export-spread 10
  cache type synchronized
  record FLOW_RECORD_MPLS
  ip flow monitor FLOW_MONITOR_IPV4 input

```

```
ipv6 flow monitor FLOW_MONITOR_IPV6 input
```

We will also configure a basic sampler. This collects 1 out of N packets based on some self-explanatory algorithm (fixed, random, etc) and adds them to the cache. This is useful for conserving resources on the router as now it only needs to care about 1/nth of the traffic arriving per flow. The sampler is applied at the interface level when we apply the monitor; it is not nested inside the FNF constructs defined earlier.

```
! CSR5
sampler FLOW_SAMPLER_MPLS
mode random 1 out-of 4
```

I illustrate one significant drawback of FNF; when you make an error or otherwise need to make a change, you have to undo many things. When I try to apply this policy to the interface facing CSR6, I am notified that I am missing a key field in the record to support export spreading. To correct it, I must remove the monitor from the interface and the record from the flow, make the correction, and reconfigure the linkages.

```
! CSR5
interface GigabitEthernet2.556
 mpls flow monitor FLOW_MONITOR_MPLS sampler FLOW_SAMPLER_MPLS output

% Flow Monitor: Flow Monitor 'FLOW_MONITOR_MPLS' [MONITOR:FLOW_MONITOR_MPLS]
Spread interval requires 'timestamp absolute monitor start' field to be
configured as a key field in the record.
```

After making the corrections, I apply the policy to both MPLS interfaces on CSR5. The cache is currently empty.

```
! CSR5
interface GigabitEthernet2.556
 mpls flow monitor FLOW_MONITOR_MPLS sampler FLOW_SAMPLER_MPLS output
```

```
R5#show flow monitor FLOW_MONITOR_MPLS cache
Cache type:                               Synchronized (Platform cache)
Cache size:                               200000
Current entries:                           0
High Watermark:                           0

Flows added:                              0
Flows aged:                               0
Synchronized timeout (secs):               30
```

There are no cache entries to display.

I open up two telnet sessions from CSR7. One goes to XRv4 and one goes to XRv3. One uses IPv4 and one uses IPv6, but that is totally irrelevant because we are only capturing MPLS-encapsulated packets.

Using the record format, I can see both flows. We will examine the label stacks shortly. Notice that the byte/packet counters are quite low; this is because we are only sampling 25% of the traffic.

```
R7#telnet 10.13.13.13 /source loopback0
```

```
R7#telnet ::10:14:14:14
```

```
R5#show flow monitor FLOW_MONITOR_MPLS cache
```

```
Cache type:                               Synchronized (Platform cache)
Cache size:                               200000
Current entries:                           2
High Watermark:                           2

Flows added:                               6
Flows aged:                               4
Synchronized timeout (secs):              30
```

```
MPLS LABEL 1:          6000   /6
MPLS LABEL 2:          92005  /6*
MPLS LABEL 3:           0     /0
TIMESTAMP MONITOR START: 22:49:00.000
counter bytes:          891
counter packets:        13
```

```
MPLS LABEL 1:          91005  /6*
MPLS LABEL 2:           0     /0
MPLS LABEL 3:           0     /0
TIMESTAMP MONITOR START: 22:49:00.000
counter bytes:          749
counter packets:         9
```

The first flow has a two label stack. The 92000-range of labels are allocated by XRv2, so we assume this is the VPNv4 label for 10.13.13.13. The label 6000 is the LDP label from CSR6 to reach XRv2's loopback 23.0.0.12/32.

```
R5#show bgp vpnv4 unicast vrf SHR 10.13.13.13/32 | include label
      mpls labels in/out nlabel/92005
```

```
R5#show mpls ldp bindings 23.0.0.12 32 neighbor 23.0.0.6
lib entry: 23.0.0.12/32, rev 34
remote binding: lsr: 23.0.0.6:0, label: 6000
```

We can confirm this by checking the FIB for the exact CEF match as well. Since CSR5 can load-share between XRv1 and CSR6, we prove that CSR6 was indeed selected. CSR7's post-NAT IP address can be gleaned from the DHCP binding database on CSR5 (CSR7 DHCP client-id is 0BADBEEF from the EEM lab).

```
R5#show ip dhcp binding | include beef
10.5.7.105      0bad.beef      MON 22 2015 11:01 PM      Automatic  Active      Gig2.557
```

```
R5#show ip cef vrf SHR exact-route 10.5.7.105 10.13.13.13
10.5.7.105 -> 10.13.13.13 => label 92005 label 6000*TAG adj out of
GigabitEthernet2.556, addr 23.5.6.6
```

The second flow has a single label from XRv1, presumably the VPNv6 label. There is no transport label due to PHP as the routers are directly connected (CSR5 is the penultimate hop).

```
R5#show bgp vpnv6 unicast vrf SHR ::10:14:14:14/128 | include label
mpls labels in/out nolabel/91005
```

```
R5#show mpls ldp bindings 23.0.0.11 32 neighbor 23.0.0.11
lib entry: 23.0.0.11/32, rev 6
remote binding: lsr: 23.0.0.11:0, label: imp-null
```

```
R5#show ipv6 cef vrf SHR ::10:14:14:14/128
::10:14:14:14/128
nexthop 23.5.11.11 GigabitEthernet2.551 label 91005
```

In both flows, also notice the MPLS EXP set to 6, which is correct for telnet traffic. The asterisk following some labels likely means that the S-bit is set, but I have asked Cisco to confirm this with no answer. It is not well documented. I have personally witnessed the asterisk on top-most labels in other relatively new versions as well. Below I show the final result of the cache after all entries have been exported per the synchronization timer. All of the flows have aged and been exported, and presumably spread over the first ten seconds of the next interval.

```
R5#show flow monitor FLOW_MONITOR_MPLS cache
Cache type:                               Synchronized (Platform cache)
Cache size:                               200000
Current entries:                           0
High Watermark:                           2

Flows added:                              16
Flows aged:                               16
Synchronized timeout (secs):              30
```

There are no cache entries to display.

Looking at the details of the exporter templates, we can see what the FNF records will look like. For each flow monitor (assuming it has a different record), a new template is created to fit the recorded components into a datagram of sorts. The second and third tables display the templates for IPv6 and MPLS respectfully. The tables also show the length of each field in bytes, plus the offset from the beginning of the recorded data. The record size is shown in the header data and is also measured in bytes. There is also a table for the “options” we enabled which allows the input VRF information to be included in the exported packets.

R5#show flow exporter FLOW_EXPORTER_COMMON_V9 templates

Flow Exporter FLOW_EXPORTER_COMMON_V9:

Client: Option options vrf-id-name-table

Exporter Format: NetFlow Version 9

Template ID : 257

timestamp absolute monitoring-interval	359	9	8
counter bytes	1	17	4

counter packets		2		21		4	

A final verification command that is very powerful shows us the policies applied to each interface. We can see the monitor name, direction, address-family, and any kind of sampler applied. You can apply multiple monitors on the same interface in both directions, which I demonstrate in some capacity below.

```
R5#show flow interface
Interface GigabitEthernet2.551
  FNF:  monitor:      FLOW_MONITOR_MPLS
        direction:    Output
        traffic(mpls): sampler FLOW_SAMPLER_MPLS
Interface GigabitEthernet2.556
  FNF:  monitor:      FLOW_MONITOR_MPLS
        direction:    Output
        traffic(mpls): sampler FLOW_SAMPLER_MPLS
Interface GigabitEthernet2.557
  FNF:  monitor:      FLOW_MONITOR_IPV4
        direction:    Input
        traffic(ip):   on
  FNF:  monitor:      FLOW_MONITOR_IPV6
        direction:    Input
        traffic(ipv6): on
```

46.2 IPFIX

IP Flow Information eXport is meant to standardize the mechanism by which flows are exported. Although Cisco allowed many other vendors to implement its Netflow solution, IPFIX adds many improvements over the original specification. Specifically, it is designed to work in secure environments using Datagram Transport Layer Security (DTLS) connectivity between collector and measurement devices versus ordinary UDP. It also calls for use of Stream Control Transmission Protocol (SCTP), Partially-Reliable SCTP (PR-SCTP), or TCP for transport to the collector; the best IPFIX designs are supported to use reliable transport.

IPFIX is defined in RFC 5470 and introduces some new terms to Netflow. Existing definitions like traffic flow, flow key, record, and others were defined earlier and are not repeated. New terms are below.

Observation Point: A place in the network where packets can be observed. It could be a shared medium (LAN), single port on a device, or a set of ports on many devices. This would be the place where Netflow is actually configured. The concept of OP's is hierarchical as a line-card could be one OP where each port on that LC are also OPs.

Observation Domain: This is the largest set of OPs available (hierarchically, the largest collection); thus, an observation domain consists of many OPs. The line-card itself might be the OD if the ports are all OPs,

and each OD has a domain ID which uniquely identifies the domain. In this way, exported records have traceability.

IPFIX is broken down into three main processes which occur sequentially:

1. **Metering process:** The inputs for this process include packet headers and other relevant Netflow data at an OP, along with any packet treatment at the OP (for example, a routing decision that yields a specific outgoing interface, assuming that field was captured). The output of this process is a flow record.
2. **Exporting Process:** This process sends flow records to one or more collecting processes. The devices that host exporting processes are called “exporters”. This is where transport details, such as ports and protocols, are specified.
3. **Collecting Process:** This process receives flow records from one or more exporting processes. The collecting process might take some action based on the records, store them, or simply discard them. The RFC does not specify an action. A device that hosts collecting processes is called a “collector” and would be the target of the aforementioned export sessions.

In terms of configuration, XE only appears to support UDP at this time and none of the recommended security features. Below, we set the export-protocol to IPFIX (sometimes called Netflow v10) and adjust the UDP port for variety.

```
! CSR5
flow exporter FLOW_EXPORTER_IPFIX
 destination 10.31.5.209 vrf MGMT
 source GigabitEthernet1
 transport udp 9996
 export-protocol ipfix

R5#show flow exporter FLOW_EXPORTER_IPFIX
Flow Exporter FLOW_EXPORTER_IPFIX:
  Description:                User defined
  Export protocol:             IPFIX (Version 10)
  Transport Configuration:
    Destination IP address:    10.31.5.209
    VRF label:                 MGMT
    Source IP address:         10.31.5.205
    Source Interface:          GigabitEthernet1
    Transport Protocol:        UDP
    Destination Port:          9996
    Source Port:               54711
    DSCP:                      0x0
    TTL:                       255
    Output Features:           Used
```

We apply this exporter to the IPv4 monitor, but in order to do it, we must remove the flow monitor from all interfaces first. After reapplying it, we can ensure it was added properly (removal/re-add not shown).

```
R5#show flow interface gig2.557 | section IPV4
```

```
  FNF:  monitor:      FLOW_MONITOR_IPV4
        direction:    Input
        traffic(ip):   on
```

```
R5#show flow monitor FLOW_MONITOR_IPV4 | include Exporter
```

```
  Flow Exporter:      FLOW_EXPORTER_IPFIX
```

We can also look at the dynamically created templates for this exporter. The template ID is 259 and there is a new column called “Ent.ID”. This was not present in the v9 templates. I assume this is for future capability; RFC 6759 suggests this is an “Enterprise ID” used for layer 7 flow identification.

```
R5#show flow exporter FLOW_EXPORTER_IPFIX templates
```

```
Flow Exporter FLOW_EXPORTER_IPFIX:
```

```
Client: Flow Monitor FLOW_MONITOR_IPV4
```

```
  Exporter Format: IPFIX (Version 10)
```

```
  Template ID      : 259
```

```
  Source ID        : 768
```

```
  Record Size      : 18
```

```
  Template layout
```

Field	ID	Ent.ID	Offset	Size
ipv4 source address	8		0	4
ipv4 destination address	12		4	4
ip dscp	195		8	1
ip protocol	4		9	1
transport source-port	7		10	2
transport destination-port	11		12	2
interface input snmp	10		14	4

47. Describe, implement, and troubleshoot IP SLA

47.1 Basic IP SLA probes, responders, features, and configurations

IP SLA is a feature that is used to actively probe network targets to gather desired statistics. This commonly includes basic reachability, latency, jitter, and even more advanced application operations like DNS lookups or HTTP GETs. In many deployments, a basic ICMP-echo operation is used to test reachability, and depending on the result, perform some action. This document will detail many of the lesser known/advanced features also. The square brackets will encompass a number in the description of each test to denote the IP SLA identifier, such as [ID 1]. Numbers will not be re-used on different routers for additional exclusivity and clarity. The network was kept simple since there are differences between IOS and XE code trains with respect to support IP SLA probes.

In this test, we have 2 CSR and 2 XRV routers in a square so that we can test all the combinations of IP SLA probers and responders. EIGRP is enabled on all nodes for basic reachability between loopbacks (not shown). A distribute-list is applied everywhere so that only loopbacks are advertised; this is the functional equivalent of OSPF's "prefix-suppression" feature. We will begin with a simple probe on CSR1 to track reachability to CSR2's loopback via the connected interface [ID 1]. We use the "source-interface" to set the source IP of the packet, but this does not force the probe to exit via that interface.

```

! CSR1
ip sla 1
  icmp-echo 153.2.2.2 source-interface GigabitEthernet2.512
  frequency 5
ip sla schedule 1 life forever start-time now

```

The reason this probe actually tracks the proper connected interfaces is because of our EIGRP distribute-list; CSR2 does not have a route back to the CSR1-CSR2 subnet if the link fails or is shutdown, so the probe fails. It isn't a fail-safe way to test a link; normally we would ping the connected interface, but for demonstration purposes, I used this roundabout method. ICMP-echoes are the simplest form of IP SLA and will not be discussed in greater detail.

```

R1#show ip sla statistics 1 | include Number
Number of successes: 3
Number of failures: 0

```

When I break the link between CSR1 and CSR2 (not shown), the probe fails. CSR1 still has reachability to the probe target but CSR2 cannot reply.

```

R1#show ip sla statistics 1 | include Number
Number of successes: 5
Number of failures: 15

```

TCP and UDP based probes are also very useful. ICMP is easy and automatic because routers send echo-replies when an echo is destined to a local interface. With TCP/UDP, more coordination is required, such as listening on specific layer 4 ports. IP SLA has an automatic (and also a manual) mechanism for

responding to TCP/UDP probes; the aptly-named IP SLA “responder” feature. When enabled with no options on CSR2, it will automatically reply to any IP SLA operation targeted to the router upon which the responder was configured.

```
! CSR2
ip sla responder
```

This raises the question of how the router determines the difference between an IP SLA probe and an ordinary data flow. IP SLA uses UDP port 1967 for signaling/control when using TCP/UDP probes. These control packets are sent first to establish communications with the remote end, then the data flow using the specific TCP/UDP ports follow. A “TCP-connect” operation [ID 2] has been configured on CSR1 to test TCP reachability to CSR2’s loopback on port 55555.

```
! CSR1
ip sla 2
  tcp-connect 153.2.2.2 55555 source-ip 153.1.1.1
  timeout 5000
  frequency 5
ip sla schedule 2 life forever start-time now
```

Enabling “debug ip sla trace” on CSR1 reveals the general operation. The control message is sent first to notify the IP SLA responder about the probe details as we configured them. This includes the target IP addresses, layer 4 port, and other information. The IP SLA responder process then expects a TCP packet with appropriate destination IP address and port information as specified in the control message. The TCP connect probe succeeds with a round-trip time (RTT) of 68 ms. Without the responder enabled on CSR2, the router would not have been listening on TCP 55555 and the packet would have been rejected.

```
R1#debug ip sla trace
IP SLAs(2) Scheduler: Starting an operation
IP SLAs(2) CtrlMsg: Sending msg, ver=1, id=15, len=52, cmd=3, ip=153.2.2.2,
port=55555, duration=5000ms
IP SLAs(2) CtrlMsg: Receive status = 0
IP SLAs(2) tcpConnect operation: Sending tcp packet
IP SLAs(2) tcpConnect operation: RTT=68

R1#show ip sla statistics 2 | include RTT|Number
Round Trip Time (RTT) for Index 2
  Latest RTT: 68 milliseconds
Number of successes: 32
Number of failures: 0
```

Because this control signaling is dynamic, some extra security would be useful. We can authenticate the control messages, too. Simply apply a key-chain in global configuration mode to the IP SLA process. In this example, we apply the key-chain only to CSR1, and the operation fails. Notice that the trace debug

also gives us a non-zero receive status, which in many cases indicates an error. Although it doesn't tell us the exact reason, we can use the show command to reveal the fault.

! CSR1

```
key chain KC_IP_SLA
  key 1
    key-string IP_SLA

ip sla key-chain KC_IP_SLA
```

```
R1#debug ip sla trace
IP SLAs(2) CtrlMsg: Receive status = 2
```

```
R1#show ip sla statistics 2 | include return|Number
Latest operation return code: Authentication failure
Number of successes: 52
Number of failures: 7
```

To see the error in real-time via debug, the routers support another debug specific to error messages.

```
R1#debug ip sla error
IPSLA-OPER_ERROR: OPER: 2 Processing video control: status = SLA_AUTH_FAIL
```

On the responder side, the debug reveals an authentication failure as well. The control message contained two commands: one for the probe details and one for authentication. On the XE routers, you must use the digit "0" after the debug command to invoke IP SLA responder debugging (not shown).

```
R2#debug ip sla trace
Ver: 1 ID: 82 Len: 52
cmd: command: RTT_CMD_TCP_CONN_ENABLE, ip: 153.2.2.2, port: 55555, duration:
5000
cmd: command: RTT_CMD_AUTH
IP SLAs responder: authentication failure
```

Once we add the same authentication configuration to CSR2 (not shown), the responder side, everything works as expected. The authentication configuration is identical on the probe sender and responder. The debug on CSR2 shows that the "hash insert" occurred, indicating successful authentication. The hash is removed after the operation completes. Some platforms will not show this debug, though, and "debug ip sla error" can be used instead to troubleshoot failures.

```
R2#debug ip sla trace
Ver: 1 ID: 128 Len: 52
cmd: command: RTT_CMD_TCP_CONN_ENABLE, ip: 153.2.2.2, port: 55555, duration:
5000
cmd: command: RTT_CMD_AUTH
IP SLAs hash insert : 153.2.2.2 55555
```

```
IP SLAs RESP: starting expTimer and hashTimer, duration = 5000
cleaning up port (153.2.2.2,55555)
IP SLAs hash remove: 153.2.2.2 55555
```

Another useful command to view IP SLA responder statistics is shown below. Notice that it shows successful IP SLA sources (probers) as well as invalid ones. It even reveals that the root of the issue was an authentication failure. This is handy for troubleshooting unexpected IP SLA failures.

```
R2#show ip sla responder
IP SLAs Responder is: Enabled
Number of control message received: 106 Number of errors: 50
Recent sources:
  153.1.1.1 [00:42:49.223 UTC Fri Mar 1 2002]
  153.1.1.1 [00:42:44.215 UTC Fri Mar 1 2002]
  153.1.1.1 [00:42:39.227 UTC Fri Mar 1 2002]
  153.1.1.1 [00:42:34.215 UTC Fri Mar 1 2002]
  153.1.1.1 [00:42:29.223 UTC Fri Mar 1 2002]

  153.1.1.1 [00:42:14.215 UTC Fri Mar 1 2002]    RTT_AUTH_FAIL
```

Let's test in the UDP-echo probes reverse direction. We know that we need IP SLA responder on CSR1, but we can also use a manual method. The authentication configured above was only for the control messages. We can configure IP SLA probes to suppress this control mechanism and only send traffic on the designated port, which will be 55556 in this example [ID 3]. Without the control, dynamic responses are not possible, and CSR1 must be configured for a specific IP address and layer 4 port pairing to which responses are allowed. **Key point: The IP address and port specified here are the destination address and the destination port of the probe.**

```
! CSR1
ip sla responder udp-echo ipaddress 153.1.1.1 port 55556

! CSR2
ip sla 3
  udp-echo 153.1.1.1 55556 control disable
  frequency 5
ip sla schedule 2 life forever start-time now
```

Notice that CSR2 does not send any control messages, just the UDP packet. This is also valuable for generating synthetic traffic on a specific TCP/UDP port; without control messages, the TCP/UDP packets are sent immediately. When testing QoS or ACLs, for example, generating traffic on key TCP/UDP ports without dealing with the IP SLA control mechanisms is made easy using this method.

```
R2#debug ip sla trace
```

```

IP SLAs(3) Scheduler: Starting an operation
IP SLAs(3) udpEcho Operation: VRF:          lookup table id: 0
IP SLAs hash insert : 153.1.2.2 55682
IP SLAs(3) udpEcho Operation: Sending udp packet
IP SLAs(3) udpEcho Operation: RTT=20
IP SLAs hash remove: 153.1.2.2 55682

```

CSR1 does not display any debug output this time because IP SLA responder (dynamic mode) is disabled. There are no control messages to process or control replies to send. CSR1 only responds to the specific UDP port and IP address pair specified. Instead, we can verify the static responder using the basic show command.

```

R1#show ip sla responder
IP SLAs Responder is: Disabled

```

```

udpEcho Responder:
  IP Address      Port
  153.1.1.1      55556

```

Finally, we can verify the probes are actually successful on CSR2.

```

R2#show ip sla statistics 3 | include Number
Number of successes: 41
Number of failures: 0

```

By setting a memory threshold on IP SLA, you can limit the number of probes that can be created. This is valuable when you are using some dynamic entities that might create many probes at will, such as Performance Routing (PFR) or some kind of SDN/PCE controller. In this test, we will check how many free bytes we have for “processor”, set the IP SLA memory threshold to that value, then try to make a new IP SLA. The router tells us we have reached our maximum limit (it doesn’t tell us exactly why).

```

R1#show memory statistics

```

	Head	Total (b)	Used (b)	Free (b)
Processor	6613F920	154915328	20544804	134370524
I/O	F400000	12582912	4124712	8458200

```

R1(config)#ip sla low-memory 134370524
R1(config)#ip sla 999
%Already at System Maximum Number of Entries of 16

```

If we clear or lower the limit, we can create new IP SLAs. On IOS XE, this limit does not seem to be as strict, as the memory management intelligence on XE is superior to that of IOS. On XE, you can still create many IP SLAs as their memory is shared differently.

```

R1(config)#no ip sla low-memory
R1(config)#ip sla 999

```

```
R1(config-ip-sla)#
```

To see the default low-memory watermark, as well as other general IP SLA information (probe counts supported operations, chronological information, etc) use the following command. The default low watermark is about 20% of the total memory, so IP SLA can continue allocating memory until that watermark is reached. Notice that the difference between the estimated system max (24775) and the number of configurable operations (24759) is equal to the number of entries configured (16). We didn't configure 16 real probes yet; I simply added dummy probes (not shown) to use more memory. Likewise, the sum of the active, pending, and inactive entries will always equal the number of entries configured.

```
R1#show ip sla application
      IP Service Level Agreements
Version: Round Trip Time MIB 2.2.0, Infrastructure Engine-II
Time of last change in whole IP SLAs: 00:59:39.879 UTC Fri Mar 1 2002
Estimated system max number of entries: 24775

Estimated number of configurable operations: 24759
Number of Entries configured      : 16
Number of active Entries          : 0
Number of pending Entries         : 0
Number of inactive Entries        : 16

pseudowirePing, y1731Delay, y1731Loss, udpApp, wspApp, mcast
generic

[snip]
```

IP SLA can also be configured to notify the SNMP-server process via traps for any relevant log messages. The SNMP-server process also needs to be configured to enable "ipsla" traps in order for it to work. This

configuration assumes you already have an SNMP-server somewhere with a trap-host configured; I quickly specify CSR2 as a dummy SNMP server. Using SNMP with IP SLA also requires a reaction-configuration, which tells IP SLA what to do what a certain probe result is seen. In this example, we reuse IP SLA ID 2 (TCP-connect operation) and tell IP SLA to generate a trap when the connection fails, and to do so upon the first failure. The logger works in the opposite direction and will log when the probe starts working again, but it does not log successive failures or successes.

```
! CSR1
ip sla logging traps
snmp-server enable traps ipsla
snmp-server host 153.2.2.2 COMMUNITY

ip sla reaction-configuration 2 react connectionLoss action-type trapOnly
threshold-type immediate
```

Let's start the probe then shut down CSR2's loopback while debugging SNMP packets. Starting the probe and shutting down the loopback are not shown for brevity. The debugs are shown in green with syslog messages in yellow.

```
R1#debug snmp packet
%RTT-4-OPER_CLOSE: condition occurred, entry number = 2
SNMP: Queuing packet to 153.2.2.2
SNMP: V1 Trap, ent rttMonNotificationsPrefix, addr 153.1.1.1, gentrap 6,
spectrap 1
[snip]

%RTT-3-IPSLATHRESHOLD: IP SLAs(2): Threshold Occurred for connectionLoss
```

If we bring CSR2's loopback back up, we should see another reaction event. Specifically, the syslog messages tells us the reaction event was "cleared", whereas the failure of the probe used "occurred". Another trap is sent to notify the SNMP server of the state change.

```
! CSR1
%RTT-4-OPER_CLOSE: condition cleared, entry number = 2
SNMP: Queuing packet to 153.2.2.2
SNMP: V1 Trap, ent rttMonNotificationsPrefix, addr 153.1.2.1, gentrap 6,
spectrap 1
[snip]
%RTT-3-IPSLATHRESHOLD: IP SLAs(2): Threshold Cleared for connectionLoss
```

As a quick discussion, the reaction-configuration has many other configuration parameters. Below are a few configuration snippets of useful reactions but I'm not going to paste outputs from their tests. The first example reacts to RTT when it rises above 5000 ms or falls below 200 ms. It sends an SNMP trap (seen earlier) and also triggers a second event (to be discussed shortly). The thresholds, both rising and falling, are only breached if 2 out of every 3 probes cross the threshold.

```
! Sample
ip sla reaction-configuration 1 react rtt threshold-value 5000 200 action-
type trapAndTrigger threshold-type xOfy 2 3
```

The next example reacts when a probe times out. Notice there is no threshold-value for the timeout variable; “timeout” is a yes/no result, unlike RTT. No SNMP trap is sent, but a follow-on action is triggered. The threshold is only crossed when the average probe result over 5 attempts differs from the status quo. If the probe is up, and there are 3 consecutive failures, then regardless of the previous or next 2 attempts, the reaction occurs due to probe failure.

```
! Sample
ip sla reaction-configuration 3 react timeout action-type triggerOnly
threshold-type average 5
```

Reaction-trigger is a tool to initiate different probes when a threshold is crossed. Below is an example; we re-use IP SLA ID 2 from earlier to test TCP-connection state to CSR2 loopback on port 55555. If this probe fails 2 times in a row, we do not want to issue a trap, but want to start IP SLA ID 1 to just ping CSR2’s loopback for 60 seconds. The logic is that even if we can’t established a TCP-connection, we can at least see if the address is reachable using ping. This implies that IP SLA ID 1’s start-time is “pending”, which means it will not begin until the IP SLA process automatically starts it. The IP SLA start/run times are not discussed in detail because they are self-explanatory, with the exception of the “pending” keyword. The syntax of the “reaction-trigger” command expects the source probe first [ID 2] and the follow-on probe second [ID 1].

```
! CSR1
ip sla reaction-trigger 2 1
ip sla schedule 1 life 60 start-time pending
ip sla reaction-configuration 2 react connectionLoss threshold-type
consecutive 2 action-type triggerOnly
```

IP SLA ID 2 appears to be working correctly so far, which means IP SLA ID 1 isn’t running.

```
R1#show ip sla statistics 2 | include Number
Number of successes: 15
Number of failures: 0
```

Let’s temporarily stop making CSR2 a dynamic IP SLA responder then watch the probe fail while debugging IP SLA trace.

```
! CSR2 (temporary)
no ip sla responder
```

We expect the ICMP-echo probe to work, though. Remember that we must wait for 2 consecutive TCP-connection failures before IP SLA will start the trigger probe.

```
R1#show ip sla statistics 2 | include Number|return_code
Latest operation return code: No connection
Number of successes: 93
Number of failures: 2
```

The trigger mechanism begins and we see a syslog message indicating that we crossed the rising threshold for connection loss. Also notice that the router set the start-time for IP SLA ID 1 to “now” after we configured it as pending initially. Note: the word “pending” may not show in the configuration, depending on the version, but the backup probe must be scheduled as shown earlier. The debug shows IP SLA ID 1 sending an ICMP echo to 132.2.2.2 (CSR2 loopback0) from 153.1.2.1 (CSR1 connected link) as expected.

```
! CSR1
%RTT-3-IPSLATHRESHOLD: IP SLAs(2): Threshold Occurred for connectionLoss
```

```
R1#debug ip sla trace 1
IPSLA-INFRA_TRACE:OPER:1 SLA_SCHED_START_TYPE_NOW
IPSLA-INFRA_TRACE:OPER:1 Starting an operation
IPSLA-OPER_TRACE:OPER:1 Starting icmpecho operation - destAddr=153.2.2.2,
sAddr=153.1.2.1
```

The ICMP-echo probe was successful, and we can see watch the lifetime decrement. After the IP SLA ID 1 probe ends, we can still view the statistics until we restart the probe or reboot the router. We see exactly 12 probes because we set the frequency to 5 seconds and ran the probe for 60 seconds only. The operation time to live is now zero, which means the probe has completed.

```
R1#show ip sla statistics 1 | include Number|^Operation
Number of successes: 2
Number of failures: 0
Operation time to live: 51 sec
```

```
R1#show ip sla statistics 1 | include Number|^Operation
Number of successes: 12
Number of failures: 0
Operation time to live: 0
```

IP SLA operations are not always just pass/fail. There are actually three non-error options that can be returned: OK (success), timeout (fail), and over threshold. The first two are self-explanatory and we have seen them many times already. Because there is a second probe timer value known as “threshold”, we can classify a probe as being somewhere between pass and fail. Threshold must be less or equal to timeout as it represents a more aggressive measurement. As an example, we can probe a link to check its status. If the RTT is greater than 100 ms, IP SLA considers this over threshold, and I might prefer alternative routing paths or take some actions. If the RTT is greater than 200 ms, I may consider the link unusable and take some other action. If the probe returns a value between 100 ms (threshold) and 200 ms (timeout), the probe is considered “over threshold”. The actions taken are a result of tracked objects

discussed in another section, but the timers themselves are functions of IP SLA. A somewhat useless IP SLA is used for demonstration here to avoid adding policers and data-plane traffic conditioning unrelated to this section. I have modified IP SLA ID 1 to have a threshold of 0 ms and a timeout of 5000 ms.

```
! CSR1
ip sla 1
  icmp-echo 153.2.2.2 source-interface GigabitEthernet2.512
  frequency 5
  threshold 0
  timeout 5000
ip sla schedule 1 life forever start-time now
```

We can confirm these changes using the show command below. With the probe running, we can see an RTT of 4 ms, which is over threshold but under timeout. Even with a very fast RTT of 4ms, the IP SLA fails. The “over-threshold” condition is considered a failure to IP SLA, much like the timeout, but IP SLA records this as “over threshold”.

```
R1#show ip sla configuration 1 | include Threshold|timeout
Operation timeout (milliseconds): 5000
Threshold (milliseconds): 0
```

```
R1#show ip sla statistics 1 | include Number|code|RTT
Round Trip Time (RTT) for Index 1
  Latest RTT: 4 milliseconds
Latest operation return code: Over threshold
Number of successes: 0
Number of failures: 5
```

We can demonstrate a forced timeout by reducing the timer to a very low number (0 in this case). Notice how an RTT is not even recorded because after the timeout is exceeded, IP SLA stops keeping track of that probe and considers it totally failed. This could occur when using IP SLA to test HTTP downloads as larger files may complete successfully but fail to do so in a timely manner. Although not terribly granular, this third option (pass, fail, or over threshold) is very useful. In later sections, we will see how object tracking can differentiate between “over threshold” and “timeout” conditions.

```
R1#show ip sla configuration 1 | include Threshold|timeout
Operation timeout (milliseconds): 0
Threshold (milliseconds): 0
```

```
R1#show ip sla statistics 1 | include Number|code|RTT
Round Trip Time (RTT) for Index 1
  Latest RTT: NoConnection/Busy/Timeout
Latest operation return code: Timeout
Number of successes: 0
Number of failures: 3
```

47.2 UDP-jitter and VOIP codec probes

The next probe to examine is the UDP-jitter. This special probe gives us extra information about the probe, such as jitter, delay, MOS, etc. It is still UDP-based and requires a similar responder configuration, but the synthetic traffic is very different from a UDP-echo probe. We configure a new IP SLA on CSR2 [ID 4] and a corresponding static IP SLA responder on CSR1. When configuring the IP SLA initially, we are presented with several numerical options, some of which are new.

```
R2(config-ip-sla)#udp-jitter 153.1.1.1 55557 ?
interval      Inter Packet Interval ! (T, 10 msec)
num-packets   Number of Packets to be transmitted ! (N, 10 pkts)
```

```
R2(config-ip-sla-jitter)#?
IP SLAs jitter Configuration Commands:
frequency          Frequency of an operation ! (F, 60 sec)
request-data-size  Request data size ! (S, 10 bytes)
```

Cisco's documentation summarizes this very concisely: "The UDP jitter operation sends N number of UDP packets, each of size S, T milliseconds apart, from a source device to a destination device, at a given frequency of F". I've added the letters to each variable just for visualization along with the default values; the parser doesn't show it. Keep in mind that "S" is the payload size, so the default packet size is 38 bytes (20 IP + 8 UDP + 10 payload). To make a more complicated example, we will make a probe that sends 200 packets, spaced 25 ms apart, every 10 seconds. Each packet should be exactly 100 bytes, therefore $S = 100 - 28 = 72$. We know that it takes 5 seconds just to send the packets ($200 * 25 \text{ ms} = 5000 \text{ ms}$), so it does not make sense to make F less than 5, although the parser does not seem to complain if you try. A UDP-jitter static responder is configured identically to a UDP-echo one; CSR1 just needs the destination IP address and port number in order to respond. The final configuration is shown below.

```
! CSR1
ip sla responder udp-echo ipaddress 153.1.1.1 port 55557

! CSR2
ip sla 4
  udp-jitter 153.1.1.1 55557 control disable num-packets 200 interval 25
  request-data-size 72
  frequency 10
ip sla schedule 2 life forever start-time now
```

The output from the statistics show command is very long now as the UDP-jitter operation attempts to collect several pieces of information. The full output is below. We can see a valid RTT, which we also achieved with the UDP-echo and ICMP-echo probe. All other fields are zero, which is not valuable. So

far, this probe has not given us any new information. Clearly the probe is capable of providing this information, so our configuration needs to be fixed.

```
R2#show ip sla statistics 4
Round Trip Time (RTT) for Index 4
  Latest RTT: 22 milliseconds
Latest operation start time: *01:21:34.675 UTC Fri Mar 1 2002
Latest operation return code: OK
RTT Values:
  Number Of RTT: 200      RTT Min/Avg/Max: 4/22/52 milliseconds
Latency one-way time:
  Number of Latency one-way Samples: 0
  Source to Destination Latency one way Min/Avg/Max: 0/0/0 milliseconds
  Destination to Source Latency one way Min/Avg/Max: 0/0/0 milliseconds
Jitter Time:
  Number of SD Jitter Samples: 0
  Number of DS Jitter Samples: 0
  Source to Destination Jitter Min/Avg/Max: 0/0/0 milliseconds
  Destination to Source Jitter Min/Avg/Max: 0/0/0 milliseconds
Packet Loss Values:
  Loss Source to Destination: 0      Loss Destination to Source: 0
  Out Of Sequence: 0 Tail Drop: 0
  Packet Late Arrival: 0 Packet Skipped: 0
Voice Score Values:
  Calculated Planning Impairment Factor (ICPIF): 0
  Mean Opinion Score (MOS): 0
Number of successes: 5
Number of failures: 0
Operation time to live: Forever
```

The key is knowing that the two IP SLA endpoints MUST be synchronized via NTP in order to resolve one-way latency. Cisco clearly states this in their documentation but it is commonly forgotten. I will make CSR1 an NTP master and CSR2 will reference time from CSR1. Before continuing, we ensure the routers synchronize time correctly.

```
! CSR1
ntp master
```

```
! CSR2
ntp server 153.1.1.1
```

```
R1#show ntp status | include ^sync
Clock is synchronized, stratum 10, reference is 127.127.7.1
```

```
R2#show ntp status | include ^sync
Clock is synchronized, stratum 11, reference is 153.1.1.1
```

Once NTP is synchronized, we now see populated one-way delay values, but not jitter.

```

R2#show ip sla statistics 4 | section Latency|Jitter
Latency one-way time:
    Number of Latency one-way Samples: 199
    Source to Destination Latency one way Min/Avg/Max: 1/15/42 milliseconds
    Destination to Source Latency one way Min/Avg/Max: 2/9/35 milliseconds
Jitter Time:
    Number of SD Jitter Samples: 0
    Number of DS Jitter Samples: 0
    Source to Destination Jitter Min/Avg/Max: 0/0/0 milliseconds
    Destination to Source Jitter Min/Avg/Max: 0/0/0 milliseconds

```

In order to record jitter values, you MUST use a dynamic IP SLA probe with a dynamic responder on the remote end. This requirement is not as well documented and is even easier to overlook. To prove it, a new IP SLA [ID 5] has been added to CSR1 to probe CSR2's loopback for delay/jitter measurements. It has the same parameters as the previous one but in the opposite direction because CSR2 was previously configured as a dynamic IP SLA responder. CSR2's configuration is shown again for reinforcement.

```

! CSR1
ip sla 5
    udp-jitter 153.2.2.2 55558 num-packets 200 interval 25
    request-data-size 72
    frequency 10
ip sla schedule 5 life forever start-time now

! CSR2
ip sla responder

```

Notice that CSR1 has the jitter information within the trace information for IP SLA ID 5, but CSR2 does not for IP SLA ID 4.

```

R1#debug ip sla trace
IP SLAs(5) jitter operation: V1, verifying sequence numbers
IP SLAs(5) jitter operation: seq=28, jitterOut=-2
IP SLAs(5) jitter operation: seq=28, jitterIn=3
IP SLAs(5) jitter operation: sourceSeq: 30, destSeq: 30
IP SLAs(5) jitter operation: ST: 5448089, RT: 5448087, DT: 0, CT: 5448103
IP SLAs(5) jitter operation: seq=29, rtt=14

R2#debug ip sla trace
IP SLAs(4) jitter operation: sourceSeq: 87, destSeq: 0
IP SLAs(4) jitter operation: ST: 5548401, RT: 5548435, DT: 0, CT: 5548429
IP SLAs(4) jitter operation: seq=86, rtt=28

```

Checking CSR1's statistics for this new probe, we can see that both latency and jitter are being properly resolved.

```

R1#show ip sla statistics 5 | section Jitter|Latency
Latency one-way time:
    Number of Latency one-way Samples: 112
    Source to Destination Latency one way Min/Avg/Max: 2/5/22 milliseconds
    Destination to Source Latency one way Min/Avg/Max: 22/31/54 milliseconds
Jitter Time:
    Number of SD Jitter Samples: 199
    Number of DS Jitter Samples: 199
    Source to Destination Jitter Min/Avg/Max: 0/6/36 milliseconds
    Destination to Source Jitter Min/Avg/Max: 0/4/16 milliseconds

```

One final interesting note is that if we break NTP synchronization, we still get jitter measurements (due to the dynamic responder), but no longer one-way delay measurements.

```

! CSR1
no ntp
ip sla restart 5

```

```

R1#show ip sla statistics 5 | section Jitter|Latency
Latency one-way time:
    Number of Latency one-way Samples: 0
    Source to Destination Latency one way Min/Avg/Max: 0/0/0 milliseconds
    Destination to Source Latency one way Min/Avg/Max: 0/0/0 milliseconds
Jitter Time:
    Number of SD Jitter Samples: 199
    Number of DS Jitter Samples: 199
    Source to Destination Jitter Min/Avg/Max: 0/4/28 milliseconds
    Destination to Source Jitter Min/Avg/Max: 0/4/12 milliseconds

```

In summary, there are 4 possible outcomes with respect to resolving latency and jitter using UDP-jitter IP SLAs. Personally, I would always have time synchronized at a minimum, and using a static/dynamic responder is really a design choice.

1. **Get statistics for both latency and jitter/MOS:** Need NTP sync with dynamic IP SLA responder
2. **Get statistics for jitter/MOS only:** No NTP sync with dynamic IP SLA responder
3. **Get statistics for latency only:** Need NTP sync with static IP SLA responder
4. **Get statistics for neither (RTT only):** No NTP sync with static IP SLA responder

You can also use UDP-jitter probes to test mean opinion score (MOS) for IP telephony purposes. This requires a dynamic IP SLA responder as mentioned above. Built-in codecs include G.729A, G.711alaw, and G.711ulaw. The table below shows the default values for these codecs as implemented by IP SLA, and in many cases, these are appropriate for tests since they represent the codecs accurately. I would recommend reducing F in a test environment, but not less than 20 because it takes 20 seconds for the operation to complete (1000 * 20ms). The relationship between S, T, N, and F is exactly the same as described earlier. You do NOT need to account for the RTP header as the codec defaults include the 12 bytes within the value S. You also do not have to use a well-known RTP port (UDP 16384 - 32767); any

port will work.

Codec	Payload size, bytes (S)	Interval btwn pkts, ms (T)	# pkts (N)	Frequency, sec (F)
G.711ulaw	160 + 12 RTP	20	1000	60
G.711alaw	160 + 12 RTP	20	1000	60
G.729A	20 + 12 RTP	20	1000	60

A new IP SLA has been configured on CSR1 [ID 6] running G.711ulaw to CSR2 (dynamic responder) with NTP synchronized. We should see latency, jitter, and MOS computations from this probe.

```
R1#show ntp status | include ^sync
Clock is synchronized, stratum 8, reference is 127.127.7.1
```

```
R2#show ntp status | include ^sync
Clock is synchronized, stratum 9, reference is 153.1.1.1
```

```
! CSR1
ip sla 6
  udp-jitter 153.2.2.2 55559 codec g711ulaw
  frequency 25
ip sla schedule 6 life forever start-time now
```

A general note about jitter samples is that, in a perfect network, the value should be N-1. The reason it is not exactly N is because the first packet is meaningless to measure jitter; you need a minimum of two because jitter is a delta between latencies. So with a jitter measurement count of 999 while N = 1000, we know our jitter calculation is as accurate as possible. The same rules apply with respect to NTP sync and static/dynamic responders as demonstrated earlier. You can have latency, jitter/MOS, both, or neither depending on the state of the network.

```
R1#show ip sla statistics 6 | section Latency|Jitter|MOS
Latency one-way time:
  Number of Latency one-way Samples: 23
  Source to Destination Latency one way Min/Avg/Max: 4/5/12 milliseconds
  Destination to Source Latency one way Min/Avg/Max: 32/36/43 milliseconds
Jitter Time:
  Number of SD Jitter Samples: 999
  Number of DS Jitter Samples: 999
  Source to Destination Jitter Min/Avg/Max: 0/4/37 milliseconds
  Destination to Source Jitter Min/Avg/Max: 0/4/20 milliseconds
MOS score: 4.34
```

Another interesting parameter in the codec configuration is the “advantage factor” or “A” according to ITU-T Recommendation G.113. This is an artificial handicap that can be applied which positively affects MOS or ICPIF (an impairment measurement). The mathematical details are beyond the scope of this document, but it’s like “expectation management” where a user may acknowledge that being on a cell-phone in a remote location will be lower quality than a local land-line call. Higher advantage factors

imply a more forgiving operator (greater handicap). To test this, we will re-use pieces of IP SLA ID 6 from CSR1 that was an ordinary VOIP probe. The default advantage factor is 0, which means no forgiveness. A new VOIP probe has been added to CSR1 [ID 8] with similar characteristics but an advantage factor of 15. Notice that the probe has not been started yet.

```
! CSR1
ip sla 8
  udp-jitter 153.2.2.2 55560 codec g711alaw advantage-factor 15
  frequency 25
```

I have applied a temporary 64 kbps policer on CSR2 on ingress that will cause about 20% packet loss over that link. This matches UDP ports between 50000 and 60000 which can capture all of the VOIP probes used so far. This is a rudimentary way of creating a “low quality phone call”.

```
! CSR2
ip access-list extended ACL_UDP_50000
  permit udp any any range 50000 60000

class-map match-all CMAP_UDP_JITTER
  match access-group name ACL_UDP_50000

policy-map PMAP_UDP_JITTER
  class CMAP_UDP_JITTER
    police 64000

interface GigabitEthernet2.512
  service-policy input PMAP_UDP_JITTER
```

First, we will run IP SLA ID 6 and see the result on MOS and ICPIF. We can see the policer has a large negative impact and the call is much lower quality that observed earlier. Only 818/1000 packets made it through with a large impairment factor as a result. The MOS has dropped substantially also.

```
! CSR1
ip sla schedule 6 life forever start-time now
```

```
R2#show policy-map interface input
FastEthernet0/1
```

```
Service-policy input: PMAP_UDP_JITTER

Class-map: CMAP_UDP_JITTER (match-all)
  1829 packets, 391406 bytes
  5 minute offered rate 12000 bps, drop rate 4000 bps
Match: access-group name ACL_UDP_50000
police:
  cir 64000 bps, bc 2000 bytes
  conformed 1433 packets, 306662 bytes; actions:
```

```

transmit
exceeded 396 packets, 84744 bytes; actions:
drop
conformed 26000 bps, exceed 7000 bps

R1#show ip sla statistics 6 | include Number_Of_RTT|MOS|ICPIF
Number Of RTT: 818      RTT Min/Avg/Max: 1/27/56 milliseconds
Calculated Planning Impairment Factor (ICPIF): 25
MOS score: 3.50

```

When we re-run the test with a heavily handicapped VOIP probe (A = 15), the results appear more positive despite losing a few more packets (only 773/1000 succeeded). The difference in the impairment factor is exactly 15 (25 – 10), which was our configured value of “A”. MOS improves slightly as well, and since the “O” in MOS stands for “opinion”, the advantage factor adds additional subjectivity to the measurement of voice quality.

```

! CSR1
ip sla schedule 8 life forever start-time now

R1#show ip sla statistics 8 | include Number_Of_RTT|MOS|ICPIF
Number Of RTT: 773      RTT Min/Avg/Max: 4/29/53 milliseconds
Calculated Planning Impairment Factor (ICPIF): 10
MOS score: 4.09

```

47.3 Advanced ICMP probes

This section will discuss the ICMP-jitter, path-jitter, and path-echo probes. These are ICMP-based probes that do not require any kind of IP SLA responder, much like the basic ICMP-echo probe. To be clear, the path-echo probe is essentially a traceroute probe, which uses UDP probes on ports starting at 33434 to determine the routing path. The context-sensitive help considers it an ICMP-based operation because the unreachable that come back are ICMP messages. Likewise, the path-jitter relies on traceroute functionality also. Compared to the UDP-jitter probes, the ICMP-jitter and path-jitter operations cannot resolve MOS or ICPIF.

ICMP-jitter works similarly to UDP-jitter except the default value for the inter-packet interval (T) is 20 ms (like the codec IP SLAs) versus 10 ms for a generic UDP-jitter probe. Our example on CSR1 [ID 9] uses N=25 and T=20. We can control the probe frequency (F) from the IP SLA also, but we cannot control the payload size (S). With our configured parameters for N and T, the probe will require 500 ms to run, so an F value of 2 seconds should be sufficient. Because a responder is never required, jitter measurements are always captured. So long as you don’t need VOIP-type parameter resolution, ICMP-jitter is a good option if the target device is inside of a different administrative domain (perhaps you can’t access it to enable IP SLA responder, or perhaps it isn’t a Cisco router at all). The only special requirement for ICMP-jitter is that ICMP timestamp-requests must transit from prober to target, and timestamp-replies must transit back. Ensure any data-plane filters in the path are configured appropriately. This feature is NOT

supported in XE and this test was conducted using IOS version 12.4T. For XE platforms, use the path-jitter or UDP-jitter options instead. These probes are examined later.

```
! CSR1
ip sla 9
  icmp-jitter 153.2.2.2 num-packets 25
  timeout 2000
  frequency 2
ip sla schedule 9 life forever start-time now

R1#show ip sla statistics 9 | section Latency|Jitter
Type of operation:      icmpJitter
Latency one-way time:
  Number of Latency one-way Samples: 3
  Source to Destination Latency one way Min/Avg/Max: 0/4/10
  Destination to Source Latency one way Min/Avg/Max: 24/27/30
Jitter Time:
  Number of SD Jitter Samples: 24
  Number of DS Jitter Samples: 24
  Source to Destination Jitter Min/Avg/Max: 0/2/8
  Destination to Source Jitter Min/Avg/Max: 0/3/13
```

Just like the UDP-jitter probe, if NTP is not synchronized, ICMP-jitter does not attempt to resolve one-way latency. I temporarily disable NTP on CSR1 (not shown) to demonstrate this.

```
R1#show ntp status
%NTP is not enabled.

R1#show ip sla statistics 9 | section Latency|Jitter
Type of operation:      icmpJitter
Latency one-way time:
  Number of Latency one-way Samples: 0
  Source to Destination Latency one way Min/Avg/Max: 0/0/0
  Destination to Source Latency one way Min/Avg/Max: 0/0/0
Jitter Time:
  Number of SD Jitter Samples: 24
  Number of DS Jitter Samples: 24
  Source to Destination Jitter Min/Avg/Max: 0/6/33
  Destination to Source Jitter Min/Avg/Max: 0/3/21
```

The next probe is the path-echo. This feature introduces some new parameters, including the ability to encode loose-source-routing (LSR) options into the IP header. CSR1 has a path-echo probe [ID 10] targeting CSR2's loopback and the connected interface towards CSR2 has been shutdown. The probe doesn't give us much information (with the ordinary show commands) other than whether the traceroute worked or not. It can be used for determining if traceroute works on a given path, which might be useful to continuously test firewall policies or other data-plane filters. EIGRP routing has been modified so that CSR2 has reachability to the transit link between CSR1 and XRv3 (not shown).

```

! CSR1
ip sla 10
  path-echo 153.2.2.2
  threshold 50
  timeout 100
  frequency 10
ip sla schedule 10 life forever start-time now

```

```

R1#traceroute 153.2.2.2
Type escape sequence to abort.
Tracing the route to 153.2.2.2
VRF info: (vrf in name/id, vrf out name/id)
 1 153.1.13.13 [MPLS: Label 93003 Exp 0] 5 msec 4 msec 3 msec
 2 153.13.14.14 [MPLS: Label 94003 Exp 0] 2 msec 4 msec 3 msec
 3 153.2.14.2 3 msec 3 msec 3 msec

```

```

R1#show ip sla statistics 10 | include Number
Number of successes: 23
Number of failures: 0

```

Next, I disable ICMP unreachable on CSR2 so that it cannot send a port-unreachable back to CSR1. CSR1 can see the intermediate hops (they send time-expired messages) but not the final hop.

```

! CSR2
interface GigabitEthernet2.524
  no ip unreachable

R1#traceroute 153.2.2.2
Type escape sequence to abort.
Tracing the route to 153.2.2.2
VRF info: (vrf in name/id, vrf out name/id)
 1 153.1.13.13 [MPLS: Label 93003 Exp 0] 5 msec 3 msec 5 msec
 2 153.13.14.14 [MPLS: Label 94003 Exp 0] 12 msec 3 msec 3 msec
 3 * * *
[snip]

```

This IP SLA probes takes a long time to actually resolve, just like a default traceroute. It sends 3 probes out a few seconds apart with increasing TTLs until TTL reaches 64. Here are a few debug samples while the probe was running. Personally, I don't consider this useful if you have to watch debugs all day to see the result.

```

R1#debug ip sla trace 10
IPSLA-OPER_TRACE:OPER:10 Return Value of T for target 0.0.0.0
IPSLA-OPER_TRACE:OPER:10 Sending Packet to 153.2.2.2 with ttl = 64
[snip]
IPSLA-INFRA_TRACE:OPER:10 Starting an operation
IPSLA-OPER_TRACE:OPER:10 Sending a pathEcho operation

```

```
IPSLA-OPER_TRACE:OPER:10 hop count = 2
IPSLA-OPER_TRACE:OPER:10 Sending Packet to 153.2.2.2 with ttl = 1
```

```
R1#show ip sla statistics 10 | include Number
Number of successes: 11
Number of failures: 0
```

To be discussed later is the concept of history and aggregated statistics. The path-echo relies entirely upon that to be useful. We will quickly re-test this probe and examine the aggregated statistics. The topology is a square again and CSR1 routes to CSR2 directly (link is brought up). We start the probe and allow it to succeed a few times. We can check its path status using a new command.

```
R1#traceroute 153.2.2.2 source 153.1.1.1
Type escape sequence to abort.
Tracing the route to 153.2.2.2
VRF info: (vrf in name/id, vrf out name/id)
 1 153.1.2.2 3 msec 1 msec 1 msec
```

```
R1#show ip sla statistics aggregated 10
IPSLAs aggregated statistics
```

```
IPSLA operation id: 10

Path Index: 1
Hop in Path Index: 1
Type of operation: path-echo
Number of successes: 2
Number of failures: 0
Target Address 153.1.2.2
```

Let's leave the probe running but shutdown the link to CSR2. Now, we should route via XRv3 and XRv4. Notice that the probe has a new path index number, along with each hop in the path, plus the target address. Because we did not restart or delete the IP SLA completely, the old statistics remain. Each "path-index" represents a unique path in the network. In our case, index 1 was the direct CSR1 > CSR2 path, while index 2 is CSR1 > XRv3 > XRv4 > CSR2. The hop indices represent reach hop within the path-index construct.

```
R1#traceroute 153.2.2.2 source 153.1.1.1
Type escape sequence to abort.
Tracing the route to 153.2.2.2

Number of failures: 0
Target Address 153.2.14.2
```

Similar to the path-echo is the path-jitter. This can also be controlled by the loose-source-routing (LSR) IP option, but will display jitter on a hop-by-hop basis. This can be useful for testing the jitter along each hop in the path cumulatively. This operation is a two-step process. First, the IP SLA performs a traceroute operation to determine the path. The IP addresses returned from traceroute are then used as targets for an ordinary ICMP-echo operation. For this test, I have shut down the link CSR1 and CSR2, forcing traffic to route through XRv3 and XRv4.

```
R1#traceroute 153.2.2.2 source loopback 0
```

```
Type escape sequence to abort.
Tracing the route to 153.2.2.2
```

```
 1 153.1.13.13 [MPLS: Label 93002 Exp 0] 44 msec 72 msec 72 msec
```

```
2 153.13.14.14 [MPLS: Label 94000 Exp 0] 84 msec 60 msec 84 msec
3 153.2.14.2 72 msec 56 msec 84 msec
```

The IP addresses returned from this traceroute are now targets of individual probes that are not explicitly shown. They are revealed with debug commands, but beware that the debugs are quite noisy with this operation. The debug states how many echoes it is sending to a specific hop, and shows every echo and echo-reply. The probe [ID 11] is shown below with no fancy options.

```
! CSR1
ip sla 11
  path-jitter 153.2.2.2 source-ip 153.1.1.1
  frequency 5
ip sla schedule 11 life forever start-time now
```

I've shown the first two echoes in yellow and green as a demonstration. Basically, this is an enhanced traceroute that discovers the path, probes each hop, and reports statistics per hop [ID 11]. The router must have reachability to individual hops. Even though the traceroute works without having reachability to the transit links, the path-jitter will fail to collect statistics for any hop for which reachability is lacking. Thus, the EIGRP distribute-lists remain disabled for this test. The debug output below shows one of the hops in the path and the probes going to it; I did not show all three. Yellow represents one probe while green represents a second.

```
R1#debug ip sla trace 11
  IP SLAs PathJitter(11): Sending 10 echos to 153.2.14.2
  IP SLAs PathJitter(11): send echo id 9511 (seq 0)
  IP SLAs PathJitter(11): send echo id 9512 (seq 1)
  IP SLAs PathJitter(11): recv reply id 9511 (seq 0)
  IP SLAs PathJitter(11): send echo id 9513 (seq 2)
  IP SLAs PathJitter(11): recv reply id 9512 (seq 1)
[snip]
```

After the probes are collected, the debug also reveals statistics about that hop. This is the same information available from the detailed statistics show command. Notice in the shown command below that all hops in the path are displayed as individual records. The output is very long so I omit redundant details to illustrate the point.

```
R1#debug ip sla trace 11

[snip]
```

We can fine-tune the probe count and inter-packet interval; the defaults are 10 probes spaced 20 ms apart. We can also direct the IP SLA to only collect statistics for the target and not hops along the path. A new IP SLA [ID 12] has been configured on CSR1 to demonstrate these options. With “targetOnly”, the final destination is the only hop, and the router will not probe intermediate hops.

```
! CSR1
ip sla 12
  path-jitter 153.2.2.2 source-ip 153.1.1.1 num-packets 4 interval 25
  targetOnly
  frequency 5
ip sla schedule 2 life forever start-time now
```

The design choice for using this option versus an ordinary ICMP-jitter operation is that this relies on ordinary UDP traceroute probes and subsequent ICMP echoes; ICMP timestamp messages are not required. Data-plane filters may have exceptions for common utilities like ping/traceroute; such exceptions are less common for ICMP timestamp messages.

```
R1#debug ip sla trace

47.4 MPLS probes

IP SLA is also a key component of MPLS OAM. Reference the “MPLS OAM” section of this document to

familiarize yourself with MPLS ping and traceroute operations before continuing. MPLS ping and traceroute operations are supported per LSP and the IP SLA configuration generally mirrors the normal exec commands for each of these features.

With CSR1 still routing to CSR2 via XRv3 and XRv4, let's quickly do an MPLS traceroute and ensure the LSP is in working order. This proves that the connected link between CSR1 and CSR2 is currently down. The output below shows 'L' for labeled output interface and a final exclamation mark indicating the LSP was constructed successfully. Note: "mpls oam" must be enabled on XE and XR platforms. It's on by default in XE but not XR. MPLS OAM is discussed more in another section, and these tests assume you have a general familiarity with MPLS OAM.

```
R1#traceroute mpls ipv4 153.2.2.2/32 source 153.1.1.1
Tracing MPLS Label Switched Path to 153.2.2.2/32, timeout is 2 seconds

Type escape sequence to abort.
 0 153.1.13.1 MRU 1500 [Labels: 93002 Exp: 0]
 L 1 153.1.13.13 MRU 1500 [Labels: 94000 Exp: 0] 16 ms
 L 2 153.13.14.14 MRU 1504 [Labels: implicit-null Exp: 0] 48 ms
 ! 3 153.2.14.2 68 ms
```

Now we configure an MPLS ping IP SLA operation to continuously test this LSP [ID 13]. Again, many of the extended options are not specific to IP SLA but are specific to MPLS OAM and are discussed later. Notice that the target of the probe is a FEC (IPv4 prefix and mask), not just an IP address.

```
! CSR1
ip sla 13
 mpls lsp ping ipv4 153.2.2.2 255.255.255.255 source-ipaddr 153.1.1.1
 frequency 5
ip sla schedule 13 life forever start-time now

R1#show ip sla statistics 13 | include Number
Number of successes: 3
Number of failures: 0
```

We will break the LSP by temporarily disabling LDP label advertisement on CSR2 completely. At this point, XRv4 has no label for 153.2.2.2/32 and cannot label-switch traffic towards CSR2. The IP SLA reports failures, which effectively alerts the user that the LSP has failed. ICMP-echo would report a false-positive in this case as IP reachability is not degraded.

```
! CSR2
no mpls ldp advertise-labels

R1#show ip sla statistics 13 | include Number
Number of successes: 10
Number of failures: 5
```

A quick MPLS traceroute and MPLS ping clearly reveals the problem; XRv4 is trying to use an unlabeled interface ("B" flag) to reach CSR2 and the IP SLA probe has properly reported it. Before continuing, we enable LDP label advertisement on CSR2 again to repair the MPLS network (not shown).

```
R1#traceroute mpls ipv4 153.2.2.2/32 source 153.1.1.1
Tracing MPLS Label Switched Path to 153.2.2.2/32, timeout is 2 seconds
[snip]
```

```
Type escape sequence to abort.
 0 153.1.13.1 MRU 1500 [Labels: 93002 Exp: 0]

B 2 153.13.14.14 MRU 1504 [No Label] 48 ms
[snip]
```

```
R1#ping mpls ipv4 153.2.2.2/32 source 153.1.1.1
Sending 5, 100-byte MPLS Echos to 153.2.2.2/32,
      timeout is 2 seconds, send interval is 0 msec:
[snip]
Type escape sequence to abort.
BBBBB
```

Next we will configure the MPLS traceroute probe on CSR1 to trace the LSP to CSR2's loopback [ID 14]. Note that some of the IP SLA parameters for MPLS traceroute are similar to the path-echo probe examined earlier, such as statistics and history kept.

```
! CSR1
ip sla 14
 mpls lsp trace ipv4 153.2.2.2 255.255.255.255 force-explicit-null source-
ipaddr 153.1.1.1
 frequency 10
ip sla schedule 2 life forever start-time now
```

This probe works the same way except it tests an MPLS path. MPLS ping does not require MPLS OAM to be enabled on transit devices (like XRv3 and XRv4), but MPLS traceroute does. This is because intermediate hops must process the OAM messages and respond, rather than just label-switch them. The probe is currently working.

```
R1#show ip sla statistics 14 | include Number
Number of successes: 2
Number of failures: 0
```

Next, I temporarily disable MPLS OAM on XRv4. We expect the traceroute to fail when TTL=2 since XRv4 is the second hop in the path from CSR1 to CSR2.

```
! XRv4
no mpls oam
```

```
R1#traceroute mpls ipv4 153.2.2.2/32 source 153.1.1.1
[snip]
```

Type escape sequence to abort.

```
0 153.1.13.1 MRU 1500 [Labels: 93003 Exp: 0]
L 1 153.1.13.13 MRU 1500 [Labels: 94003 Exp: 0] 9 ms
. 2 *
! 3 153.2.14.2 5 ms
```

```
R1#debug ip sla trace 14
```

```
IPSLA-OPER_TRACE:OPER:14 Sending Packet to 153.2.2.2 with TTL value of 2
IPSLA-OPER_TRACE:OPER:14 Return Value of '.' for target 153.2.2.2
IPSLA-OPER_TRACE:OPER:14 Timeout Return value '.'
```

Just like the path-echo, the probe seems to never actually fail, and watching the debug can be time-consuming. Remember, the MPLS ping still works even with OAM disabled on the transit routers.

```
R1#ping mpls ipv4 153.2.2.2/32 source 153.1.1.1
[snip]
```

Type escape sequence to abort.

```
!!!!
Success rate is 100 percent (5/5), round-trip min/avg/max = 4/5/10 ms
Total Time Elapsed 26 ms
```

Using the aggregate statistics show commands, we see the LSP information hop-by-hop. The network has been restored with all links enabled and MPLS OAM active everywhere. The probe begins by following the one-hop LSP directly to CSR2. It's hardly an LSP given the implicit-null label, but it does qualify. Then, after shutting down that CSR1-CSR2 connected link, a second LSP is discovered via XRv3 and XRv4. These outputs are nearly identical to those seen in the path-echo except the type of probe is "lsp trace" versus "path-echo". I've highlighted the path indices and hop indices to illustrate. Notice there were a few failures of the LSP trace during IGP convergence (green), but this isn't significant.

```
R1#show ip sla statistics aggregated 14

47.5 Ethernet probes including ITU-T Y.1731 Basics and Performing Monitoring (PM)

The ITU-T defined Y.1731 for large-scale carrier Ethernet network management and performance monitoring (PM). This is almost identical in operation to IEEE 802.3ag (CFM) described earlier, except it uses different terms to describe certain maintenance components. The real benefit of Y.1731 is the addition of PM, which comes in the form of some additional signaling parameters and IP SLA probes. Although not specific to IP SLA probes, we will briefly discuss the Y.1731 terminology and configure some Y.1731 features before testing probes.

Maintenance Entity Group (MEG): This is equivalent to a CFM maintenance association (MA). A MEG/MA is a set of MEPs that are all part of the same service instance (MEG/MA identifier, or MEGID/MAID) and domain. Each MEP must have a unique MPID within the MEG/MA. The only difference is that a MAID can be up to 43 characters while a MEGID is limited to 13. The CCMs sent by MEPs within a MEG/MA carry the MEGID/MAID as seen in the Ethernet OAM section.

Alarm Indication Signal (AIS): Though discussed in the CFM section casually, this is actually a Y.1731 feature that enhances CFM. It is enabled by default and is used to signal alarms in a carrier Ethernet network. If a link fails, the switch that sees the failure will signal AIS to other switches in the MEG/MA.

Remote Defect Indication (RDI): This was also discussed in the CFM section and is a complementary function of AIS. The remote switches with MEPs in a MEG/MA will set the RDI bit in their CCMs when sending traffic back towards the failure. This assists with fault isolation and notifies other MEPs that a failure has occurred somewhere in the domain. The absence of RDI CCMs indicates no failure, and since RDI is carried in CCMs, CCMs must be enabled for RDI to work.

Lock status (LCK): This was not discussed in the CFM section and is another type of signaling using in Y.1731. Unlike AIS, LCK does not signify an error condition but is treated similarly as AIS upon receipt at a MEP. Data is interrupted and the Ethernet service breaks, but this allows the MEP to differentiate between a real failure (AIS) and an administrative decision (LCK). This is useful for troubleshooting or simply “shutting down” a MEP.

Service/server MEP (SMEP): Explained briefly, this is an interface which reports fault conditions whether it is actually a MEP or not. This is mostly relevant for verification and show commands.

We will use the CFM/E-LMI lab from earlier as it contains an existing CFM, OAM, and E-LMI architecture. Y.1731 can work alongside any of these protocols and no combination of them is mutually exclusive; Y.1731 and its PM feature set actually require CFM since the two are virtually the same.

Briefing reviewing the switched network, ME1 and ME2 are switches that are owned by an operator. Given limited hardware quantity, this is the “provider” network as well. ME2 is the UPE towards ME3, which is the CE, and provides Ethernet services on UNI ports 13 and 14. These service VLANs 13 and 14, respectively, which have CFM MEPs on ME1 (simulated remote CE) and ME3. ME1 would service the “other end” of these VLAN 13 and VLAN 14 connections if I had more hardware. Between ME2 and ME3, Ethernet OAM is running on port 13 only while E-LMI is running on both ports 13 and 14.

On ME2, we will adjust some basic timers on dummy ports. These settings can also be applied globally, and we can completely turn off AIS and LCK signaling (we won’t since the network is so small). On port 4, we totally disable AIS/LCK signaling, and on port 5, we adjust the timers. There are two options for timers, 60 seconds and 1 second. Cisco recommends 60 seconds when there are many VLANs in use, and 1 second when they are few VLANs in use; the default is 60 for both AIS and LCK. When an event occurs, AIS is signaled immediately, but follow on messages are sent at the specified interval. The default level at which AIS/LCK signaling is transmitted is the level of the MIP on that interface. Since these dummy links are “operator” links, I add them as level 1 MIPs. Port 5 adjusts the CFM level for AIS/LCK transmission as

well, and since MIPs will forward higher-level information, this allows for broader dissemination if desired.

```
! ME2
interface FastEthernet0/4
  ethernet cfm mip level 1 vlan 1-4094
  no ethernet cfm lck link-status
  no ethernet cfm ais link-status

interface FastEthernet0/5
  ethernet cfm mip level 1 vlan 1-4094
  ethernet cfm lck link-status period 1
  ethernet cfm lck link-status level 3
  ethernet cfm ais link-status period 1
  ethernet cfm ais link-status level 3
```

We can verify this by checking the service MEP (SMEP) show command. The confusing thing about Y.1731 configuration is that it is mostly rolled into the “CFM” parser construct. This streamlines configuration but makes it more challenging to differentiate between 802.1ag and Y.1731 feature sets.

```
ME2#show ethernet cfm smep interface f0/4
SMEP Settings:
-----
Interface: FastEthernet0/4
LCK-Status: Disabled
LCK Period: 60000 (ms)
Level to transmit LCK: Default
AIS-Status: Disabled
AIS Period: 60000 (ms)
Level to transmit AIS: Default
Defect Condition: No Defect
```

```
ME2#show ethernet cfm smep interface f0/5
SMEP Settings:
-----
Interface: FastEthernet0/5
LCK-Status: Enabled
LCK Period: 1000 (ms)
Level to transmit LCK: 3
AIS-Status: Enabled
AIS Period: 1000 (ms)
Level to transmit AIS: 3
Defect Condition: No Defect
```

On ME2, we will check the default parameters on the NNI LACP bond to ME1 and a UNI port to ME3 for completeness. We can see that the port-type has no affect on the default Y.1731 configurations as the AIS/LCK periods are still 60 seconds with the CFM level equal to the MIP level per interface.

```
ME2#show ethernet cfm smep interface port-channel 12
```

```

```

```
Defect Condition: No Defect
```

We can test the Y.1731 LCK feature as well. Let's assume that ME3, as the customer, wants to administratively "shut down" service for VLAN 13 only. Rather than shut down interfaces, adjust trunk allowed lists, or unplug cables, ME3 can raise the LCK condition. Unlike the ping or cross-check features, this command is applied against a locally-configured MEP. Below, ME3 tries to shut down the remote MEP on ME1 within a given service instance. The parser notifies us that MPID 113 is not found, which suggests the feature is local-only.

```
ME3#ethernet cfm lck start mpid 113 domain CUSTOMER service number 13
```

```
No mep with mpid 113 is configured for Domain CUSTOMER vlan 13. Command  
aborted.
```

We correct the command to reference the local MPID of 313. The associated MEP has been errdisabled on a per-VLAN basis as a result of entering LCK condition.

```
ME3#ethernet cfm lck start mpid 313 domain CUSTOMER service number 13
```

```
01:33:07: %PM-4-ERR_DISABLE_VP: vlan oos error detected on Fa0/9, vlan 13.  
Putting in err-disable state.
```

```
01:33:07: %E_CFM-6-ENTER_LCK: local mep with mpid 313 level 7 VLAN 13 dir U  
Interface Fa0/9 enters LCK defect condition
```

We can verify the errdisable state and LCK condition using some show commands. Finding the LCK condition identified as a "fault" is challenging because it isn't technically an error, so CFM doesn't report

it as such. Instead, we can look at the details for the local MEP within the particular domain/service. This shows the “Defect condition” as LCK. The reason this doesn’t register as an “error” is because this isn’t an AIS condition, and no AIS/RDI is signaled. The interface clearly shows no RDI signal.

```
ME3#show interfaces fast0/9 status
Port      Name                Status      Vlan      Duplex  Speed  Type
Fa0/9     VLAN-BASED MEP      connected   vl-err-dis a-full  a-100  10/100BaseTX
```

```
ME3#show ethernet cfm errors
[no output]
```

```
ME3#show ethernet cfm maintenance-points local detail mep domain CUSTOMER
service number 13
Local MEPs:
-----
[snip]
LCK-Status: Enabled
LCK Period: 60000(ms)
LCK Expiry Threshold: 3.5
Level to transmit LCK: Default
Defect Condition: LCK
presentRDI: FALSE
[snip]
```

Unlike an AIS condition, there is no indication of a failure on ME1 at all. The remote MEP appears fully operational, no RDI is seen in the CCMs, and loopback messages (pings) can be exchanged. From the perspective of all remote MEPs, the LCK condition is local-only, which allows an administrator to break services without causing fault propagation through the MEG/MA.

```
ME1#show ethernet cfm errors
[no output]
```

```
ME1#show ethernet cfm maintenance-points remote detail mpid 313
Version: IEEE-CFM

Age of Last CC Message(sec): 2
CC Packet Statistics: 575/0 (Received/Error)
MEP interface status: Up
MEP port status: Up
Receive RDI: FALSE
```

```
ME1#ping ethernet mpid 313 domain CUSTOMER service number 13
Type escape sequence to abort.
Sending 5 Ethernet CFM loopback messages to 001f.9d0b.1680, timeout is 5
seconds:!!!!
Success rate is 100 percent (5/5), round-trip min/avg/max = 1/2/8 ms
```

We can exit the LCK condition by using the exec command to “stop” locking the service. The interface leaves the err-disable state and the LCK condition is cleared from the local MEP details.

```
ME3#ethernet cfm lck stop mpid 313 domain CUSTOMER service number 13
01:51:12: %PM-4-ERR_RECOVER_VP: Attempting to recover from vlan oos err-
disable state on Fa0/9, vlan 13.

Level to transmit LCK: Default
Defect Condition: No Defect
```

Now, we will configure basic Ethernet probes. These are less complex than Y.1731 PM probes but are a good starting point. As the customer, ME3 wants to ensure service reachability for VLAN 13 across the carrier network. We use a basic loopback message (ping) probe to test reachability to remote MEPs on ME1 [ID 1]. The look-and-feel of this probe is very similar to an ICMP-echo examined earlier. The target is a remote MPID with the specified domain using a specific VLAN. Inside the probe details, we can adjust minor parameters shown below, such as size and CoS. We can verify success/failure using the same show command seen earlier, which makes IP SLA very powerful for a wide range of service probes.

```
! ME3
ip sla 1
  ethernet echo mpid 113 domain CUSTOMER vlan 13
  cos 2
  request-data-size 1000
  threshold 5
  timeout 50
  frequency 5
ip sla schedule 1 life forever start-time now
```

```
ME3#show ip sla statistics 1
IPSLAs Latest Operation Statistics
```

```

IPSLA operation id: 1
Type of operation: ethernet-echo
    Latest RTT: 4 milliseconds
Latest operation start time: 02:01:20 UTC Mon Mar 1 1993
Latest operation return code: OK
RTT Values:
    Number Of RTT: 1                      RTT Min/Avg/Max: 4/4/4 milliseconds
Number of successes: 16
Number of failures: 0
Operation time to live: Forever

```

Additionally, ME3 can monitor jitter across the Ethernet network as well. This is comparable to the UDP-jitter probe since it returns one-way latency, jitter, and RTT. There is no concept of MOS or impairment factor with this probe, so those are not measured. The probe sends 40 frames 25 ms apart, which takes 1000 ms (1 second) to run. Notice that the statistics, just like UDP-jitter, can resolve jitter and RTT without NTP synchronization. One-way delay requires time synchronization; we have not configured NTP yet, so the probe below cannot capture latency.

```

! ME3
ip sla 2
    ethernet jitter mpid 114 domain CUSTOMER vlan 14 num-frames 40 interval 25
    frequency 10
ip sla schedule 2 life forever start-time now

ME3#show ip sla statistics 2

```

We quickly configure NTP on all switches. Since we didn't have (or need) IP connectivity before, I also add SVIs for VLAN 14 on ME1 and ME3 to support this. ME1 and ME2 have reachability over VLAN 1 which I use for management. This will allow NTP to converge so that all switches are synchronized to ME1, and I use the fastest possible polling timers (2^4, or 16 seconds) to achieve this.

```
! ME1
interface Vlan14
 ip address 10.14.14.1 255.255.255.0

ntp master

! ME2
ntp server 10.0.10.91 min-poll 4 max-poll 4

! ME3
interface Vlan14
 ip address 10.14.14.3 255.255.255.0

ntp server 10.14.14.1 min-poll 4 max-poll 4
```

We confirm that NTP has synchronized all clocks, then check the IP SLA statistics on ME3 to ensure one-way delay can be measured. Since 40 packets are sent, all 40 can be used for latency measurements, and with jitter, exactly N-1 packets (39 in this case) can be used for jitter calculations as seen earlier.

```
ME1#show ntp status | include sync
Clock is synchronized, stratum 8, reference is 127.127.1.1
```

```
ME2#show ntp status | include sync
Clock is synchronized, stratum 9, reference is 10.0.10.91
```

```
ME3#show ntp status | include sync

  Number of Latency one-way Samples: 40
  Source to Destination Latency one way Min/Avg/Max: 0/1/6 milliseconds
  Destination to Source Latency one way Min/Avg/Max: 1/1/2 milliseconds
```

With the basic probes operational, we will configure Y.1731 PM probes. These are very specific probes defined in Y.1731 which are unlike the generic probes we just configured. The generic probes would be best used in environments where not all devices were Y.1731-capable or where only basic reachability is

required. Y.1731 provides much more detailed information as part of the larger PM picture. There are a few different types of probes/tests worth discussing first. The detailed information returned by these probes is available for viewing within the CLI parser, as well as many external management tools.

Delay Measurement (ETH-DM): This measures frame delay and frame delay variation (latency and jitter, essentially). This is accomplished by sending ETH-DM frames from source to destination MEP, then receiving ETH-DM frames in reply, which is similar to the jitter probe we saw earlier. Specific DM measurement (DMM) and DM reply (DMR) messages are used for this exchange. Somewhat similar to statistical aggregation (another IP SLA feature), DM probes will tally delay measurements into bins for statistical analysis. While the ME3400 has the syntax options for one-way delay as well, only two-way delay is supported. One-way delay uses a special message (1DM) and is a simpler process.

Frame Loss Measurement (ETH-LM): This operation is an out-of-band signaling mechanism between two MEPs to keep track of transmitted/received frames. It relies on data traffic traversing the network, and the statistical information about those frames is exchanged between MEPs. Some number of frames are transmitted and received, and the difference between the two numbers is the frame loss. Frame loss measurement and reply (FLM/FLR) messages are used to signal between the controller MEP (prober) and responder MEP (target). The only traffic generated by this probe is meant to carry signaling information between MEPs about actual data traffic statistics. As such, this feature is only valid for measuring E-LINE (P2P) services. Though the syntax exists in the ME3400 parser for this feature, it isn't supported on the platform. There are better alternatives available within the Y.1731 specification.

Synthetic Loss Measurement (ETH-SLM): This is similar to ETH-LM in objective but not in operation. This measures frame loss by generating frames (like classic IP SLA probes) rather than monitoring data traffic (like Netflow or ETH-DM). SLM measurement (SLM) and SLM reply (SLR) frames are used to carry this information. SLM improves upon ETH-LM because it works in multipoint service deployments (E-LAN and E-TREE) and serves a dual purpose; the SLM/SLR messages are used as the synthetic traffic and also carry the performance information. While the ME3400 has the syntax options for ETH-LM as well (LMM), only ETH-SLM is supported. This is a single-ended operation that is managed by the controller MEP, and since the probes also carry the loss information, it supports multipoint Ethernet services.

On ME3, we will begin with a two-way delay measurement using Y.1731 DMM/DMR frames. Unlike most IP SLAs, there are many mandatory fields within the probe definition, including CoS and source MEP/MAC address. I use MPIDs rather than MAC addresses in these examples so that the configurations will work on other physical switches. We will measure two-way delay within VLAN 13 using CoS 5, presumably to troubleshoot a VOIP issue. We can adjust the frame size in increments of 4 starting at 64 (and going up to 384) and determine the inter-frame interval, which is valuable for certain applications. The DMM measurement cannot use a frame interval less than 1000 ms, but I configure that explicitly despite it being the default. The max-delay is effectively a timeout measured in ms. The aggregation interval determines how often to aggregate results, which will make more sense when we view the output. The Y.1731 distribution bucket configuration is very flexible as well. We can custom-define the number of buckets and their upper-bounds in microseconds. In this case, I create 5 buckets for both

delay (latency) and delay-variation (jitter): 0 – 999 us, 1000 – 2999 us, 3000 – 4999 us, 5000 – 6999 us, 7000+ us. We can use the integer “-1” to specify an infinite value, which makes sense for the final bucket’s upper-bound. This information is displayed nicely in the detailed show command seen later.

```
! ME3
ip sla 10
  ethernet y1731 delay DMM domain CUSTOMER vlan 13 mpid 113 cos 5 source mpid
  313
  max-delay 10
  frame size 128
  frame interval 1000
  aggregate interval 120
  distribution delay two-way 5 1000,3000,5000,7000,-1
  distribution delay-variation two-way 5 1000,3000,5000,7000,-1
ip sla schedule 10 life forever start-time now
```

First, we will verify the configuration, to include defaults, using the basic IP SLA show command. Notice that the probe thinks the clocks are not synchronized, which means one-way delay (latency) measurements are impossible with this current probe. We will revisit this later. Also notice the frequency is 120 seconds, which is a reflection of the aggregation interval.

```
ME3#show ip sla configuration 10
IP SLAs Infrastructure Engine-III

Flag: OK

Of greater interest is the detailed output. This is where we can see our custom distribution buckets and their hit-counts, among other things. The first few stanzas of the output are identical to what we have already seen, so we won't analyze that again (output is omitted). We now get timestamps for the best and worst delay times for historical reference. I specifically customized the bins based on the latencies I knew I would see in the network so we could get better statistical distribution, rather than having everything land in one bucket. We can see that most of the time, the two way delay is between 1 ms and 3 ms, but so far, never greater than 5 ms. The delay-variation measurements include both positive and negative measurements (jitter can be positive or negative since consecutive packets are compared to one another). We can see that both positive and negative jitter measurements are almost always less than 3 ms.

Most of the debugs of these features are hidden within the CFM command set, since Y.1731 PM has been rolled into CFM (generally speaking) within the parser. I show a few debug commands for completeness, but there isn't much value in them. Most of it is very low-level information not relevant for troubleshooting. I only use these for ensuring the probe is actually working (sending frames) without trying to decode the data. The packet debug clearly shows frames being transmitted.

For comparative assessment, we will create a similar probe except this time, we will notify Y.1731 that the clocks are synchronized [ID 11]. We will apply this to VLAN 14 and adjust some other minor options

for variety. Because the clocks are “in sync”, one-way delay buckets are now available for configuration, so I add them as well. Under the statistics parameters for the previous probe, we only saw buckets for two-way delay measurements; now we see delay and delay-variation measurements for one-way delay.

We quickly check to ensure the probe thinks the clock is synchronized and that the frequency is a reflection of the 90 second aggregation interval.

```
ME3#show ip sla configuration 11 | include Clock|freq
```

Clock: In Sync

Operation frequency (seconds): 90 (not considered if randomly scheduled)

Before looking at the output, there is a command we can use to verify the configured probes within the context of CFM. On the probing device, we can see the CFM level, VLAN ID, and MAC addresses used within a probe after the MPIDs are translated into brain MACs. This is useful to see which probes are in use; note that the “basic” probes are not shown here as this only displays Y.1731 PM probes.

```
ME3#show ethernet cfm pm
```

EPM-ID	SLA-ID	Lvl/Type/ID/Cos/Dir	Src-Mac-address	Dst-Mac-address
0	10	7/Vlan/13/5/Up	001f.9d0b.1680	001d.4692.f700
1	11	7/Vlan/14/5/Up	001f.9d0b.1680	001d.4692.f700

We can see details about any session by referencing the Ethernet PM ID (EPM-ID) which is allocated by the system. This lists all of the probe configuration parameters seen in the IP SLA verification, as well as the Y.1731-specific messages used. Since this is a delay measurement probe, DMM/DMR messages are used as discussed above, while the other messages are not. Recall that 1DM messages are not supported on this platform.

The detailed output for this new probe, as expected, provides tons of useful information. With one-way delay being measured also, there is more detail available to the administrator. Technically, you could configure “clock sync” even if NTP was not configured, but this would lead to incorrect information on the switches, ultimately defeating the purpose of Y.1731 PM. This output spans several pages so comments are inserted throughout. Looking at the delay stanza, we now see 2 additional sub-sections for forward and backward one-way delay measurements. Earlier, we only had the two-way section, which didn’t require clock sync and was essentially an RTT measurement. I would have never guessed that my one-way latencies were so much different in this small lab network, but Y.1731 proves me wrong. If we sum ~800 us and ~1600 us timers, we get something close to ~2300 us which is the two-way delay average (values highlighted), so the math actually makes sense.

```
ME3#show ip sla statistics 11 details | begin ^Delay:
```

Delay:

Number of forward observations: 34

Min/Avg/Max forward: 28/859/1673 (microsec)

Time of occurrence forward:

Min - 04:18:25.606 UTC Mon Mar 1 1993

Max - 04:18:40.625 UTC Mon Mar 1 1993

Number of backward observations: 40

Min/Avg/Max backward: 550/1570/2528 (microsec)

Time of occurrence backward:

Min - 04:18:15.585 UTC Mon Mar 1 1993

Max - 04:18:20.594 UTC Mon Mar 1 1993

Number of TwoWay observations: 40

Min/Avg/Max TwoWay: 495/2281/3850 (microsec)

Time of occurrence TwoWay:

Min - 04:18:15.586 UTC Mon Mar 1 1993

Max - 04:18:05.570 UTC Mon Mar 1 1993

Next, we have three sets of delay bins per the probe configuration. We can further prove that the forward delay is much better than the backward delay. This might be cause for concern in a real network as it may indicate certain congestion at transmitting/receiving interfaces along the EVC. Two-way delay is about the same as it was for the previous probe in VLAN 13, as expected.

! ME3 continued

Bin forward:

Bin Range (microsec)	Total observations
0 - < 1200	23
1200 - < 2400	11
2400 - < 4294967295	0

Bin backward:

0 - < 1200	12
1200 - < 2400	25
2400 - < 4294967295	3

Bin TwoWay:

Bin Range (microsec)	Total observations
0 - < 1000	2
1000 - < 3000	27
3000 - < 5000	11
5000 - < 7000	0
7000 - < 4294967295	0

Next, we have the delay variance stanzas which measure jitter. This is even more verbose than the delay measurements since in addition to the direction of forward vs. backward, it introduces positive vs. negative. All 4 combinations are valid measurements which Y.1731 measures and records within the aggregation interval. Instead of 3 stanzas, there are now 6, each clearly marked. Unlike latency, the jitter appears to be more stable in both directions, generally hovering around 700-800 us.

! ME3 continued

Delay Variance:

Number of forward positive observations: 12

Max - 04:18:05.570 UTC Mon Mar 1 1993

Number of TwoWay negative observations: 18

Min/Avg/Max TwoWay negative: 2/937/1982 (microsec)

Time of occurrence TwoWay negative:

Min - 04:18:20.594 UTC Mon Mar 1 1993
Max - 04:18:05.570 UTC Mon Mar 1 1993

Next, we see the bins for the delay variation measurements. Since delay variation is very low in this network, most of the hits are in the “best” bucket which makes characterization a little more difficult. A better configuration would be to create smaller buckets, perhaps of size 500 us, to achieve finer granularity. To correspond with the 6 summary stanzas above, there are 6 different buckets. 4 of them represent one-way delay measurements for all combinations of positive/negative and forward/backward. The remaining 2 are positive/negative two-way delay variation measurements.

! ME3 continued

Bin forward positive:

Bin Range (microsec)	Total observations
0 - < 1200	10
1200 - < 2400	2
2400 - < 4294967295	0

```
5000 - < 7000 0
7000 - < 4294967295 0
```

Next, I configure a Y.1731 probe to attempt one-way delay measurement using 1DM messages [ID 12]. For simplicity, I don't adjust any other parameters since Cisco clearly states this is not supported on the ME3400. There is no need to specify clock synchronization since 1DM probes must assume this to be true, since their only purpose is one-way delay. Debugging IP SLA errors for this probe, we can see that the session never gets created. It does not register as a PM within CFM either; nothing happens.

```
! ME3
ip sla 12
  ethernet y1731 delay 1DM domain CUSTOMER vlan 13 mpid 113 cos 3 source mpid
  313
ip sla schedule 12 life forever start-time now
```

```
ME3#debug ip sla error 12
ME3(config)#ip sla schedule 12 life forever start-time now
04:49:48: IPSLA-OPER_ERROR: OPER: 12 Failed to Create Delay Session
```

```
ME3#show ethernet cfm pm
```

EPM-ID	SLA-ID	Lvl/Type/ID/Cos/Dir	Src-Mac-address	Dst-Mac-address
0	10	7/Vlan/13/5/Up	001f.9d0b.1680	001d.4692.f700
1	11	7/Vlan/14/5/Up	001f.9d0b.1680	001d.4692.f700

There is nothing in the configuration that shows an error, other than the probe simply not working. The statistics show commands work but produce no output. I assume this exists in the parser because other hardware platforms/line-cards may support it using a similar code base.

```
ME3#show ip sla configuration 12

```

Now that we have tested frame delay and delay variation extensively, we will test frame loss. We will use the synthetic loss measurement (ETH-SLM) process for this, which introduces some new options. First, we can configure faster inter-frame intervals with SLM, so I set this to 100 ms versus 1 second used for DMM tested above. 100 ms is the fastest interval that SLM can use. I reduce the aggregate interval to 3 and configure the probe to store 3 intervals worth of traffic. Every 8 consecutive frames will be checked to measure loss, and I set the frame size (payload) to the maximum value. I use CoS 1 for the probe because this example can be used to measure the loss of scavenger traffic in the network. We quickly confirm the details of the probe by checking the configuration.

```
! ME3
ip sla 20
  ethernet y1731 loss SLM domain CUSTOMER vlan 14 mpid 114 cos 1 source mpid

The detailed statistics are much less involved than delay and delay variation seen earlier. The basic statistics are omitted and I begin the output where the detailed information begins. The frame counts clearly show no loss in the network. The average frame loss ratio (FLR) is 0% as is the cumulative FLR. Minimums and maximums cannot be computed in a network with no loss. These statistics are identical for forward and backward measurements.

```

To briefly introduce some frame loss, I shut down the LACP bond on ME1. This breaks much more than just Y.1731, but I use it as a quick way to break reachability to the remote MEP from ME3's perspective. Some frames should be lost and the Y.1731 statistics show the details. We can see the cumulative FLR increasing to a very high value, which indicates almost all traffic, is being lost. However, in the reverse direction we see no fault indication. Since the link is totally broken, the remote end is not seeing any traffic and cannot reply. In the forward direction, ME3 is sending many packets but getting no replies

after shutting down the LACP bond on ME1. With numbers like this, we can infer that the network is totally broken with no connectivity between MEs.

```

Last, I attempt to configure ETH-LM which is the older mechanism of measuring frame loss using a new probe [ID 13]. The probe has no fancy options since the documentation states it isn't supported, so we don't expect it to work.

```
! ME3
ip sla 21
  ethernet y1731 loss LMM domain CUSTOMER vlan 14 mpid 114 cos 1 source mpid
  314
ip sla schedule 21 start-time now life forever
```

Just like with the 1DM probe, we will enable IP SLA debugging to confirm the feature is unsupported. IP SLA reports that it cannot create the loss session, and the Y.1731 PM session table confirms it.

```
ME3#debug ip sla error 21
ME3(config-sla-y1731-loss)#ip sla schedule 21 start-time now life forever
05:30:05: IPSLA-OPER_ERROR: OPER: 21 Failed to Create Loss Session
```

```
ME3#show ethernet cfm pm
```

```
-----
EPM-ID    SLA-ID    Lvl/Type/ID/Cos/Dir Src-Mac-address Dst-Mac-address
```

0	10	7/Vlan/13/5/Up	001f.9d0b.1680	001d.4692.f700
1	11	7/Vlan/14/5/Up	001f.9d0b.1680	001d.4692.f700
2	20	7/Vlan/14/1/Up	001f.9d0b.1680	001d.4692.f700

Configuration-wise, we see nothing wrong. The frames for this operation would be LMM/LMR as discussed earlier, assuming the feature was supported on the ME3400.

```
ME3#show ip sla configuration 21
IP SLAs Infrastructure Engine-III
Entry number: 21
Owner:
Tag:
Operation timeout (milliseconds): 5000
Ethernet Y1731 Loss Operation
Frame Type: LMM
[snip]
```

The last feature to examine is the IP SLA Ethernet-monitor. This feature automatically spawns probes for each of the MEPs within a MEG/MA. We can optionally exclude certain MEPs from this auto-discovery process or specify a subset of VLANs as well, but these are optional modifications. We specify a CFM domain and VLAN 13 for this example, plus optional threshold and CoS settings. The SLA is scheduled somewhat similar to IP SLA group scheduling (discussed in a dedicated section), since many sub-probes will be created.

```
! ME3
ip sla ethernet-monitor 30
  type echo domain CUSTOMER vlan 13
  cos 4
  threshold 500
ip sla ethernet-monitor schedule 30 schedule-period 30 start-time now
```

While configuring the probe, we can enable debugs to see what IP SLA is doing behind the scenes. After the probe is started, IP SLA considers it registered. Shortly thereafter, once it runs for the first time, it discovers a single RMEP inside VLAN 13 with MPID 113.

```
ME3#debug ip sla trace ethernet-monitor 30
IP SLAs Auto Ethernet debugging for entry 30 is on
```

```
! ME3
IPSLA-AUTOETH_TRACE:OPER:30 registered domain = CUSTOMER, vlan =
13,auto_probe = 30
IPSLA-AUTOETH_TRACE:OPER:30 Number of MPIDs discovered = 1
IPSLA-AUTOETH_TRACE:OPER:30 creating probe for domain = CUSTOMER, vlan = 13,
MPID = 113
```

Looking at the IP SLA summary, we see the original 2 probes (this does not show Y.1731 probes) with IDs 1 and 2. We then see a dynamic probe with ID 100001 which was spawned by the Ethernet monitor. This runs once every 30 seconds. This is a basic loopback message (LBM) probe, which is identical to an Ethernet-echo probe we evaluated first in this section. These spawned probes are not Y.1731-based.

```
ME3#show ip sla summary
```

```
IPSLAs Latest Operation Summary
```

```
Codes: * active, ^ inactive, ~ pending
```

ID	Type	Destination	Stats (ms)	Return Code	Last Run

*100001	ethernet-ec ho	Domain:CUSTOMER pid:113 Vlan:13	M RTT=3	OK	23 seconds ago

The statistics for the probe show that it is reachable. At a glance, this feature does not appear immediately useful, since the MEPs were already discovered by CFM. Rather than being used for discovery, it will save the administrator from having to manually configure probes. Furthermore, if MPIDs change in the network, the administrator won't have to adjust IP SLA echo probes if Ethernet-monitor is configured within that MEG/MA. The RTT time is probably the most valuable part of this output since the up/down status is CFM-managed.

```

The true value of this feature comes with the reaction-configuration. The details of this IP SLA feature as discussed in another section, but in short, this allows an administration to generate alarms when certain events occur. Ethernet-monitor reaction events only support SNMP traps and not trigger events, so we quickly enable SNMP traps for IP SLA along with IP SLA logging. I configure ME1 as a dummy SNMP

server to receive these traps so that we can see them originated by ME3 via SNMP packet debugs. I configure a basic reaction to timeout which reacts immediately and generates an SNMP trap.

```
! ME3
ip sla logging traps
snmp-server enable traps ipsla
snmp-server host 10.14.14.1 ETHMON ipsla

ip sla ethernet-monitor reaction-configuration 30 react timeout threshold-
type immediate action-type trapOnly
```

We can verify the configuration above by checking the SNMP host list (trap/inform servers) and verifying the reaction configuration was applied to the dynamic probe.

```
ME3#show snmp host
Notification host: 10.14.14.1    udp-port: 162    type: trap
user: ETHMON    security model: v1

ME3#show ip sla reaction-configuration 100001
Entry number: 100001
Index: 1
Reaction: timeout
Threshold Type: Immediate
Action Type: Trap only
```

To quickly test this, I remove VLAN 13 from the trunk allowed list on ME1 port 9. This generates an AIS alarm in CFM (unrelated to IP SLA), but more significantly it will break reachability to the RMEP. I enable SNMP packet debugging so we can confirm that an SNMP trap is sent when the IP SLA probe fails.

```
ME3#debug snmp packets
SNMP packet debugging is on

! ME1
interface FastEthernet0/9
 switchport trunk allowed vlan remove 13
```

When the timeout is first noticed, IP SLA is the first process to generate syslog messages to indicate the timeout condition for probe 100001. This triggers an SNMP trap which we can see below; this carries information about the alarm. Multiple traps might be sent based on the alarm, but I show one for brevity. We can clearly see the configuration is correct or else no traps would have appeared.

```
! ME3
01:04:33: %RTT-4-OPER_TIMEOUT: condition occurred, entry number = 100001
01:04:33: %RTT-3-IPSLATHRESHOLD: IP SLAs(100001): Threshold Occurred for
timeout
```

```

01:04:33: SNMP: Queuing packet to 10.14.14.1
01:04:33: SNMP: V1 Trap, ent rttMonNotificationsPrefix, addr 10.14.14.3,

00 00 00 00 05 4D F9 00 00 00 00 01 00 00 00 00
00 00 00 00 00 00 00 00 00 00 00 00

```

A few seconds later, the CFM errors are shown. This indicates that the remote MEP is no longer accessible which is signaled via DefRemoteCCM.

```

! ME3
01:04:36: %E_CFM-3-REMOTE_MEP_DOWN: Remote MEP mpid 113 vlan 13 MA name
number 13 in domain CUSTOMER changed state to down with event code TimeOut.
01:04:36: %E_CFM-6-ENTER_AIS: local mep with mpid 313 level 7 VLAN 13 dir U
Interface Fa0/9 enters AIS defect condition
01:04:38: %E_CFM-3-FAULT_ALARM: A fault has occurred in the network for the
local MEP having mpid 313 vlan 13 for service MA name number 13 with the
event code DefRemoteCCM.

```

Checking the IP SLA summary, the dynamic probe is gone since it is deleted when the remote MEP became inaccessible. Probe 1 was manually configured and was pinging the same remote MEP, and now it too reports a failure. The pings aren't even sent since the remote MEP doesn't exist within the specified CFM domain (that is, it is absent from the CFM database).

```

ME3#show ip sla summary
IPSLAs Latest Operation Summary
Codes: * active, ^ inactive, ~ pending

```

ID	Type	Destination	Stats (ms)	Return Code	Last Run
*1	ethernet-ec ho	Domain:CUSTOMER pid:113 Vlan:13	M RTT=0	Invalid Remote MPID	4 seconds ago
*2	ethernet-ji tter	Domain:CUSTOMER pid:114 Vlan:14	M RTT=3	OK	4 seconds ago

We will quickly repair the network by adding VLAN 13 back to ME1 port 9's trunk allowed list. A new dynamic probe is automatically created to begin monitoring the remote MEP once again. Since the reaction configuration was only tracking timeouts, IP SLA logs and SNMP traps are not generated for the restoration of service.

```
! ME1
interface FastEthernet0/9
 switchport trunk allowed vlan add 13
```

First, CFM clears all alarms since valid CCMs were received from this remote MEP.

```
! ME3
01:15:07: %E_CFM-6-EXIT_AIS: local mep with mpid 313 level 7 VLAN 13 dir U
Interface Fa0/9 exited AIS defect condition
01:15:07: %E_CFM-6-REMOTE_MEP_UP: Continuity Check message is received from a
remote MEP with mpid 113 vlan 13 MA name number 13 domain CUSTOMER interface
status Up event code Returning.
```

Next, we check the Ethernet-monitor to ensure a new probe was generated. The probe ID has been incremented, which is expected behavior when probes are added and removed. Probe ID 1 is also reporting a functional remote MEP again, which helps prove that the network has stabilized.

```
ME3#show ip sla summary

47.6 Miscellaneous probes

This section discusses less common probes, such as DHCP, HTTP, DNS, and FTP. The DHCP probe has very few options and is meant to test a DHCP server's (probe destination) ability to allocate IP addresses. In this example, we will assume there are some hosts on the LAN segment between CSR1 and XRv3. CSR1 wants to test to see if CSR2 has a matching pool for its connected interface on that LAN [ID

101]. While this is not a 100% fool-proof way of testing a DHCP server, in most cases it is fair to assume that if CSR2 has a pool that covers 153.1.13.1, it has a pool that covers the entire LAN subnet. The minimum configurable frequency value for DHCP operations is 10 seconds.

```
! CSR1
ip sla 101
  dhcp 153.2.2.2 source-ip 153.1.13.1
  frequency 10
ip sla schedule 101 life forever start-time now

! CSR2
ip dhcp pool LAN_1_13
  network 153.1.13.0 255.255.255.0
```

Once the probe is started, DHCP server debugs on CSR2 can reveal some packet details. Because the probe target may not be on the connected subnet, the DHCP prober promotes itself to a DHCP relay so that it can proxy the internally-generated DHCPDISCOVER messages to the DHCP server.

```
R2#debug ip dhcp server packet
R2#debug ip dhcp server event
DHCPD: DHCPDISCOVER received from client 0073.6161.2d31.3031.2c36 through
relay 153.1.13.1.
%DHCPD-4-PING_CONFLICT: DHCP address conflict: server pinged 153.1.13.1.
DHCPD: Adding binding to radix tree (153.1.13.2)
DHCPD: Adding binding to hash tree
DHCPD: assigned IP address 153.1.13.2 to client 0073.6161.2d31.3031.2c36.
DHCPD: Sending DHCP OFFER to client 0073.6161.2d31.3031.2c36 (153.1.13.2).
DHCPD: unicasting BOOTREPLY for client c201.0201.0000 to relay 153.1.13.1.
[snip, DHCP process continues]
```

Because IOS-based DHCP servers will attempt to ping an address before issuing it, the DHCP server allocates the next available address. Each time the probe runs, DHCP re-issues a new address, effectively iterating over the entire range of available addresses. After several iterations, we can look at the DHCP bindings on CSR2 and see the “probe’s” current address. We can see the number of DHCP successes is one less than the address assigned; this is due to the conflict since 153.1.13.1 could not be assigned. CSR1 doesn’t actually store the addresses anywhere, but CSR2 is allocating them correctly, which means the probe is successful.

```
R2#show ip dhcp binding | include 153\.
153.1.13.22 0073.6161.2d31.3031. Mar 01 2002 01:34 AM Automatic

R1#show ip sla statistics 101 | include Number
Number of successes: 21
Number of failures: 0
```

If we temporarily delete the DHCP pool for that LAN, the probe will fail. The source address specified in

the probe is the relay address and is also the input for the DHCP process. As a side note, DHCP option 82 (the information option) can also be inserted into the probe to carry the circuit-id, remote-id, or subnet-mask options. IOS DHCP server debugs and binding databases don't display this information, so a test is unwarranted. A real DHCP server would use this information as specified.

```
! CSR2
no ip dhcp pool LAN_1_13

R2#debug ip dhcp server packet
R2#debug ip dhcp server event
DHCPD: Sending notification of DISCOVER:
  DHCPD: htype 1 chaddr c201.0201.0000
  DHCPD: remote id 020a000099020e0200000000
  DHCPD: circuit id 00000000
DHCPD: DHCPDISCOVER received from client 0073.6161.2d31.3031.2c36 through
relay 153.1.13.1.
DHCPD: there is no address pool for 153.1.13.1.

R1#show ip sla statistics 101 | include Number
Number of successes: 0
Number of failures: 18
```

Next, we will examine the HTTP probe. This probe is generally used for HTTP GET requests but is very flexible in that it can handle raw requests also. HTTP syntax is beyond the scope of this test so the raw requests are not discussed in detail. CSR2 has been configured as an HTTP server with a few files on flash, route.txt and tech.txt. Let's quickly ensure that R1 can download these files.

```
R2#show ip route | redirect flash:route.txt

R2#show tech-support | redirect flash:tech.txt

R1#copy http://153.2.2.2/route.txt null:
Loading http://153.2.2.2/route.txt !
1118 bytes copied in 0.236 secs (4737 bytes/sec)

R1#copy http://153.2.2.2/tech.txt null:
Loading http://153.2.2.2/tech.txt !
236407 bytes copied in 10.764 secs (21963 bytes/sec)
```

We can clearly see the larger file took longer to download. Let's configure a pair of HTTP probes that downloads these files [ID 105, 106] using a threshold of 2 seconds with a timeout of 30 seconds

```
! CSR1
ip sla 105
  http get http://153.2.2.2/route.txt
```

```

threshold 2000
timeout 30000
ip sla schedule 105 life forever start-time now

ip sla 106
http get http://153.2.2.2/tech.txt
threshold 2000
timeout 30000
ip sla schedule 106 life forever start-time now

```

Given our previous discussion about threshold and timeout, we expect the HTTP probe downloading the route.txt file to be successful, while the probe downloading the tech.txt file should be over threshold (which counts as a failure).

```

R1#show ip sla statistics 105 | include Number|HTTP
Latest HTTP Transaction RTT: 208 ms
Number of successes: 3
Number of failures: 0

```

```

R1#show ip sla statistics 106 | include Number|HTTP
Latest HTTP Transaction RTT: 5645 ms
Number of successes: 0
Number of failures: 2

```

IP SLA HTTP operations are not smart enough to use configured HTTP usernames or passwords for authentication, unfortunately. If we enable local authentication on CSR2 with username/password http/http, we can see CSR1 can easily download a file given those credentials.

```

! CSR1
ip http client username http
ip http client password 0 http

! CSR2
ip http authentication local
username http privilege 15 password 0 http

R1#copy http://153.2.2.2/route.txt null:
Loading http://153.2.2.2/route.txt !
1118 bytes copied in 0.236 secs (4737 bytes/sec)

```

In IOS routers, we cannot figure usernames or passwords in the SLA definition, either. There appears to be no way to perform HTTP operations with authentication when using IP SLA at this time. An HTTP raw request might work but that is far beyond the scope of this document.

```

R1(config-ip-sla)#http get http://http:http@153.2.2.2/route.txt
% Bad URL

```

Even worse, in XE you can specify the username/password, but it still does not work.

```
R1(config-ip-sla)#http get http://http:http@153.2.2.2/route.txt
R1(config-ip-sla-http)#
```

Assuming we don't change the original URL string, notice how the probes are still trying to download the files but are not supplying a username or password. The most unfortunate part of this "feature" is that it leads to false positives. Notice how IP SLA ID 106 is suddenly succeeding because the HTTP operation technically completed very quickly. Earlier it was failing due to long download times, but now that the HTTP server is saying "You cannot download the file because you didn't authenticate", IP SLA considers this a success. The probe is effectively a TCP-connect operation at this point. In summary, don't use IP SLA HTTP probes to issue HTTP GET requests to servers that may require authentication. I cannot find a way to disable HTTP server authentication in XE, but it can be disabled in IOS.

```
R1#debug ip http all
its_urlhook url: /tech.txt, method 1
lds_urlhook, url=/tech.txt
Fri, 01 Mar 2002 00:24:48 GMT 153.1.13.1 /tech.txt auth_required
      Protocol = HTTP/1.0 Method = GET
```

```
R1#show ip sla statistics 106 | include Number|HTTP
Latest HTTP Transaction RTT: 111 ms
Number of successes: 2
Number of failures: 6
```

Just to prove my inability to bypass HTTP authentication, I've configured AAA and several authentication/authorization lists that say "none". This should effectively bypass HTTP authentication on XE routers and is applied to CSR2. It still does not work.

```
! CSR2
ip http authentication aaa login-authentication AAA_LOGIN_NONE
ip http authentication aaa exec-authorization AAA_EXEC_NONE
ip http authentication aaa command-authorization 15 AAA_COMMANDS_NONE

R1#debug ip http all
Sun, 05 MON 2015 18:23:44 GMT 153.1.13.1 /route.txt auth_required
      Protocol = HTTP/1.0 Method = GET
```

The DNS probe can be used to perform forward (A or AAAA record) or reverse (PTR record) lookups for a given hostname or IP address, respectively. The minimum frequency for a DNS operation is 9 seconds. Two new IP SLA probes [ID 110, 111] are built to test these two features. The first probe will request an IP address for the name "SLA_TEST.lab.local" while the second will request a hostname for "4.3.2.1". XE does not support DNS server capabilities (but does support the probe), so regular IOS 12.4T was used exclusively for this test.

```

! CSR1
ip sla 110
  dns SLA_TEST.lab.local name-server 153.2.2.2
  frequency 9
ip sla schedule 110 life forever start-time now

ip sla 111
  dns 4.3.2.1 name-server 153.2.2.2
  frequency 9
ip sla schedule 111 life forever start-time now

! CSR2 (IOS only)
ip host R2 153.2.2.2
ip host SLA_TEST.lab.local 1.2.3.4
ip host SLA_REVERSE.lab.local 4.3.2.1

```

I was not able to find any show commands to validate that these DNS lookups were successful, but the IP SLA debug reveals it. IP SLA is smart enough to determine whether an A/AAAA or PTR record resolution is required based on the user's input.

```

R1#debug ip sla trace
IP SLAs(110) Scheduler: saaSchedulerEventWakeup
IP SLAs(110) Scheduler: Starting an operation
IP SLAs(110) dns operation: Starting dns operation
IP SLAs(110) dns operation: Query name - SLA_TEST.lab.local
IP SLAs(110) dns operation: actual target queried = SLA_TEST.lab.local
IP SLAs(110) dns operation: Query return code - no error
IP SLAs(110) dns operation: received IP Address 1.2.3.4
IP SLAs(110) dns operation: RTT=73

IP SLAs(111) Scheduler: saaSchedulerEventWakeup
IP SLAs(111) Scheduler: Starting an operation
IP SLAs(111) dns operation: Starting dns operation
IP SLAs(111) dns operation: Query addr - 4.3.2.1
IP SLAs(111) dns operation: actual target queried = 1.2.3.4.in-addr.arpa
IP SLAs(111) dns operation: Query return code - no error
IP SLAs(111) dns operation: received name SLA_REVERSE.lab.local
IP SLAs(111) dns operation: RTT=59

```

An added benefit of using IP SLA for DNS testing is that I did not have to configure any name-servers or domain-names in global configuration. This means that I would not need to interrupt a working, production DNS configuration to test an unrelated DNS issue.

```

R1#show hosts | include domain
Default domain is not set

```

```

! This is a hidden command on regular IOS and XE, perhaps deprecated
R1#show ip name-servers

```

255.255.255.255

IOS routers used to support FTP server many versions ago. Rather than set up a new FTP server for this quick test, I will create a new topology using GNS3 and tap into my laptop as an FTP server. I am moderately confident that the FTP download probe works the same on XE as it would on classic IOS. So far, all of the miscellaneous probes have. Here is a small network diagram for clarity.

The aptly named router `FTP_TEST_ONLY` will download a small file from the FTP server manually, then test it with an IP SLA probe [ID 120]. The minimum frequency is 30 seconds and the default mode is passive FTP. The FTP server is 192.168.0.1 and the IOS router interface is 192.168.0.100. The FTP service requires a username/password of “ftp/ftp” to download files.

```
! FTP_TEST_ONLY
ip ftp username ftp
ip ftp password ftp

ip sla 120
  ftp get ftp://anonymous:test@192.168.0.1/config.txt
  frequency 30
ip sla schedule 120 life forever start-time now

FTP_TEST_ONLY#copy ftp://192.168.0.1/config.txt null:
Accessing ftp://192.168.0.1/config.txt...
Loading config.txt !
[OK - 881/4096 bytes]
881 bytes copied in 0.624 secs (1412 bytes/sec)
```

It looks like the Cisco decided to make the default FTP credentials “anonymous/test” for the IP SLA probe, even though I have an FTP username/password in the configuration. This is very similar to the HTTP probe issues we saw earlier where IP SLA is not talking to the FTP process.

```
FTP_TEST_ONLY#debug ip ftp
FTP: ---> USER anonymous
FTP: 331 Password required for anonymous
FTP: ---> PASS test
FTP: 530 Login or password incorrect!
FTP: ---> QUIT
FTP: 221 Goodbye
```

Interestingly, it automatically inserted that login information into the configuration. As expected, we can actually update it, unlike with HTTP. We will make a new probe for this [ID 121] using active FTP (versus passive FTP, the default). As expected, IP SLA ID 120 is failing due to authentication failure while IP SLA ID 121 is successfully downloading the target file. The key point is that the “ip ftp username” and “ip ftp password” commands in global configuration mode are totally ignored by the IP SLA FTP probes.

```
! FTP_TEST_ONLY
ip sla 120
  ftp get ftp://anonymous:test@192.168.0.1/config.txt
  frequency 30
ip sla schedule 120 life forever start-time now

ip sla 121
  ftp get ftp://ftp:ftp@192.168.0.1/config.txt mode active
  frequency 30
ip sla schedule 121 life forever start-time now

FTP_TEST_ONLY#show ip sla statistics 120 | include Number
Number of successes: 0
Number of failures: 3

FTP_TEST_ONLY#show ip sla statistics 121 | include Number
Number of successes: 4
Number of failures: 0
```

From this point on, IP SLA ID 120 is disabled. We will delete the “config.txt” file from the FTP server and see if IP SLA ID 121 returns errors. At the same time, we will confirm it’s actually broken with a manual download. The FTP operation appears quite reliable without any output deciphering required; the output below depicts newly-caused failures since the file no longer exists on the FTP server.

```
FTP_TEST_ONLY#copy ftp://192.168.0.1/config.txt null:
Accessing ftp://192.168.0.1/config.txt...

47.7 Aggregated statistics, history, group scheduling, and miscellaneous features

These next three topics are not related to each other and could be considered miscellaneous IP SLA features, but they are important nonetheless.

IP SLA history as a feature is pretty self explanatory; it tracks IP SLA statistics over time and can aggregate results. The configuration of the feature is quite involved and there isn’t a simple “on” button for it. By default, aggregated statistics are collected for a probe. Often times, it is not feasible to collect every statistical component from every probe forever; of greater interest is probably the maximum RTT,

minimum RTT, sum of all RTTs (to compute the mean/average), and sum of all squares of the RTTs (to compute standard deviation). If a probe is run indefinitely in a production network, this statistical information can be very useful to diagnose network issues, plan for growth, etc.

IP SLA statistics introduces many new terms. A “bucket” is defined a range of values, measured in ms, inside which an RTT may lie. Each time the probe returns an RTT value that fits within a bucket, the bucket counter is incremented. For example, the default bucket width is 20 ms and assume we have a custom maximum of 4 buckets. The first bucket would be $[0 \leq b1 < 20]$, the second bucket would be $[20 \leq b2 < 40]$, the third bucket would be $[40 \leq b3 < 60]$, and the fourth bucket would be $[b \geq 60]$.

Below is a list of statistical aggregation-related options with their descriptions.

distributions-of-statistics-kept: controls the number of buckets (default 1). This is limited to ICMP echo, UDP echo, TCP-connect, Path-Echo, and DNS probes.

hours-of-statistics-kept: how many hours to collect before purging old results (default 2).

statistics-distribution-interval: controls the bucket width (default 20ms). This is limited to ICMP echo, UDP echo, TCP-connect, Path-Echo, and DNS probes. These are similar to the bins/buckets discussed in the Y.1731 PM section.

It would be nice to be able to collect all statistical information for a probe for a specific troubleshooting or measurement purpose; that is, statistical aggregation is not always desirable because it is very coarse. We can use “history enhanced” for collecting additional details. This specific collection feature is not on by default, but the aggregated data is automatically collected. The aforementioned parameters are tunable but do not “enable” aggregation as it is always on. Enhanced history introduces some new variables.

enhanced interval X buckets Y: X is measured in seconds and represents how wide a bucket is. Y is simply the number of buckets, and the product $X*Y$ is how long you can collect data. To collect data for one hour, you could make 60 buckets of 60 seconds each, for a total of $60*60=3600$ seconds. X must be greater or equal to the probe frequency. Default values: $X=900$ seconds (15 minutes), $Y=100$. Buckets are circular buffers and will rewrite the oldest data with the newest data. Not to be confused with “buckets” in statistical aggregation, these buckets store a collection of results over a period of time and do not attempt to sort them.

lives-kept: A life is the duration for which a probe runs. Often times we type “life forever” without thinking, but a probe that gets started/stopped regularly is said to be starting/ending “lives”. The default is 0, which effectively means history is disabled. You must set a non-zero value to enable history for a probe.

filter: Additional options exist as to when a history event should be recorded. Self-explanatory options include all, none, overThreshold, and failures (timeout exceeded). The default is none, so you have to pick another option to collect history. This is somewhat like an “on” button for the feature.

Rather than create new probes, we can tune our existing probes to collect statistics. Let's start with IP SLA ID 1, which was our basic ICMP-echo probe. Here is our task:

1. Measure RTTs across 4 buckets of width 25 ms for aggregated statistics. This assumes that most RTTs should be within 1 to 75 ms, since anything larger than that will end up in the final bucket.
2. Keep detailed statistics for 75 minutes
3. Purge all statistics when the probe is stopped and restarted
4. Maintain detailed history for each probe, remembering as far back as 15 probes
5. Record all events

To meet those requirements, the configuration would look like this. I've added in-line comments to help clarify. Regarding the "purge" requirement, only 1 "life" is kept, so restarting the probe will purge the old statistics once the probe restarts.

```
ip sla 1
 icmp-echo 153.2.2.2 source-interface GigabitEthernet2.512
 frequency 5
 history distributions-of-statistics-kept 4      ! 4 aggregation buckets ...
 history statistics-distribution-interval 25    ! of width 25 ms
 history lives-kept 1                          ! remember stats from 1 life
 history filter all                           ! record all events
 history enhanced interval 5 buckets 15        ! hist. details, 5*15 = 75 min
```

As expected, the statistical data is a lot to read for a human. What is interesting is the history information and aggregated statistics aren't both under the "history" show command tree. Technically aggregated statistics are not history, but in newer versions of code, they are configured under the "history" tree in the IP SLA configuration. Enhanced history is specific to exact probe results. Notice in the output below that the bucket index starts at 12 and goes to 26. This is because buckets "wrap", and after we hit bucket 16, we had to forget about bucket 1 by rewriting it. There are always up to 15 buckets, as we programmed. Because we set the history interval equal to the frequency, we essentially capture one sample per interval, which goes into a single bucket. The sample time is measured in absolute ms; notice that it increases by 5000 each row. The entry number is the IP SLA ID and the life resets when the probe is restarted by the system. A manual restart using "ip sla restart [id]" will always reset the life to 1.

```
R1#show ip sla history 1
      Point by point History
Entry    = Entry number
LifeI    = Life index
BucketI  = Bucket index
SampleI  = Sample index
SampleT  = Sample start time (milliseconds)
CompT    = RTT (milliseconds)
Sense    = Response return code
```

Entry	LifeI	BucketI	SampleI	SampleT	CompT	Sense	TargetAddr
1	1	12	1	77890478	1	1	153.2.2.2
1	1	13	1	77895478	1	1	153.2.2.2

1	1	25	1	77955478	1	1	153.2.2.2
1	1	26	1	77960478	1	1	153.2.2.2

The aggregated statistics used to be displayed in a tabular fashion but is no longer. At the top, we have a summary of the usual IP SLA statistics. It gives us a more detailed breakdown as to why failures occurred also. I've separated the buckets with a newline just to increase readability. The bucket starts by stating its range in ms, followed by the average latency (it really means RTT). Notice the sum of the RTT squares; because this could potentially be a huge number, it is split into two unsigned 32-bit integers. Assuming the high-order 32-bits are 0, the low order 32-bits represent the true sum of RTT squares. If the high-order bits are not 0, then you should convert both numbers to binary, concatenate them, then convert back to decimal. A machine-friendly operation would be to left-shift the high-order number 32 times, then add the low-order number for the same result. Notice that the other 3 buckets have no values because our RTT is very fast; all returned RTTs fall into the first bucket.

```

Let's do another example with an HTTP download, reusing IP SLA ID 106 to download a large file. A quick manual test says this should take about 350 ms on a CSR1000v with the 100 kbps throughput limitation. Here are the requirements:

1. Measure RTTs within 8 buckets of maximal width for aggregated statistics
2. Keep statistics for four hours
3. Keep statistics through as many probe restarts as possible

Notice the requirements did not specify history or any of its affiliated parameters. These features are not supported for all probes, and HTTP happens to be one of them:

```
R1(config-ip-sla-http)#history filter all
%filter-for-history cannot be set for this probe
```

```
R1(config-ip-sla-http)#history lives-kept 2
%lives-of-history-kept cannot be set for this probe
```

```
R1(config-ip-sla-http)#history buckets-kept 3
%buckets-of-history-kept cannot be set for this probe
```

Here is the configuration given the aggregated statistics collection:

```
! CSR1
ip sla 106
  http get http://http:http@153.2.2.2/tech.txt
  threshold 2000
  timeout 30000
  history hours-of-statistics-kept 4
```

```
history distributions-of-statistics-kept 8
history statistics-distribution-interval 100
```

Unfortunately, we cannot test this in our current environment. Remember that XE refuses to let me disable HTTP authentication and no matter what, IP SLA will not issue the authentication parameters without a raw request. Let's look at the statistics anyway to confirm the configuration. I'm not going to show all 8 of the buckets. We do get some extra HTTP statistics since it relies both on TCP and sometimes DNS too. It is also interesting that the success counter increases despite the authentication failing on the server, as noted earlier.

Although technically not history, some probes, such as path-echo and MPLS traceroute, have some additional statistical components. The amount of memory required to store all of the statistical data for this probe is the product of “history distributions-of-statistics-kept” and all three of the following fields. Increasing or reducing any of them results in more or less memory consumed, respectively.

paths-of-statistics-kept: Maximum number of statistics paths to capture (default unknown). Each unique path discovered by the probe counts as a different path and is assigned a unique index.

hops-of-statistics-kept: Maximum number of hops to capture (default 16). Each path index has list of hops associated with it, and this specifies the maximum number of hops to be stored per path index.

samples-of-history-kept: Maximum number of history samples to collect (default 2).

Because we have already examined the path/hop probe feature earlier, trying to see the effects of all of these variables is hard in a small network. We will look at the “hops” variable since that is easiest to see by adjusting an existing probe [ID 10] on CSR1. I’ve configured the maximum hops to 2, knowing that we actually have 3 hops to the destination. Notice that the aggregated statistics only show the hops to reach XRv4, but not the final destination as we saw earlier. The probe is not allowed to capture more than 2 hops per path index, so in this case, the path is incomplete.

```
! CSR1
ip sla 10
  path-echo 153.2.2.2
  threshold 50
  timeout 100
  frequency 10
  hops-of-statistics-kept 2
  samples-of-history-kept 10
ip sla schedule 10 life forever start-time now
```

```
R1#show ip sla statistics aggregated 10

Target Address 153.13.14.14
```

Next, we progress to group scheduling. In name, this is also self-explanatory, and is a way to schedule multiple IP SLAs simultaneously. The parameters themselves can be confusing and require further explanation. Three new IP SLAs have been defined using the ICMP-echo probe [ID 152, 153, 154]. The three of them ping CSR2, XRv3, and XRv4 loopbacks and should be scheduled to run as a group but not at exactly the same time. There is nothing special about the probes themselves since this section focuses on the scheduling; notice that none of these probes have been scheduled.

```
! CSR1
ip sla 152
 icmp-echo 152.2.2.2 source-interface Loopback0
 frequency 10

ip sla 153
 icmp-echo 152.13.13.13 source-interface Loopback0
 frequency 12

ip sla 154
 icmp-echo 152.14.14.14 source-interface Loopback0
 frequency 15
```

We can use the “schedule-period” parameter to set the even interval at which probes are started. This overrides the individual probe frequency; take the schedule-period divided by the number of probes to get the new frequency (in this case, 60 sec / 3 probes = 20 sec). With timestamps enabled, we see the probes to each destination exactly 20 seconds apart. The entire group schedule [ID 150] is spaced 2 minutes apart (first set of three operations started at 22:26:28, the next one was 22:28:28) which is what the group frequency controls. This is a good approach to probe many destinations spread out over time to determine if there are any large scale failures. As a general restriction, the group frequency, just like the individual probe frequency, cannot be less than the timeout of any individual probe. The different probes are highlighted using different colors for clarify. Again, each one starts exactly 20 seconds apart.

```
! CSR1
ip sla group schedule 150 152-154 schedule-period 60 frequency 120

```

An alternative approach is to schedule them together. There is no scheduling period used for balanced distribution of probes; they are all start at the same time but still have their frequencies overwritten by the group schedule. In this case, the group frequency is 60 seconds, at which time all probes are issued at the same time. The timestamps are highlighted below to prove it. After 60 seconds, the scheduling process restarts.

```

! CSR1
ip sla group schedule 150 152-154 schedule-together frequency 60

```

You can combine the schedule-together or schedule-period options with a range of frequencies which is often called “random scheduling”. This can improve statistical metrics for measuring network performance because sampling at given intervals might yield biased results. When used with schedule-period, the initial probes are scheduled at random intervals within the bounds of the schedule-period (it is no longer a uniform spread). The specification of frequency is identical to the previous example except the interval is random within the specified range. In the “closest” case, each probe could be spaced up to 10 seconds apart with a frequency of 45 seconds, which is acceptable.

The initial scheduler starts ID 153 and ID 154 at different intervals after starting the first probe, which was ID 152. Notice that 154 had a smaller value, so it starts about a second before ID 153 in the debugs below. Each operation runs independently, and at the end, generates a new random frequency between 45 and 55 seconds. I did not enable msec granularity because it's not required to understand the technology. We can see that ID 152 restarts ~48 seconds later (23:04:22 to 23:05:10), ID 153 restarts ~51 seconds later (23:04:23 to 23:05:14), and ID 154 restarts about ~52 seconds later (23:04:23 to 23:05:15). At the end of the second set of probes where I have snipped most of the output, a new set of frequencies is generated, and the process continues. The frequency changes after each operation which is what achieves the pseudo-randomness.

```

Random scheduling with schedule-together crashes the XE router 100% of the time, so I suppose I won't be testing it. This is CSR1000v version 3.13.2S. Random scheduling with schedule-period, tested above, appears to work well and never crashes the router.

```
R1(config)#ip sla group schedule 150 152-154 schedule-together frequency  
range 45-65 start-time now life forever
```

```

[snip]
```

IP SLA automatic provisioning is a feature where probes can be automatically spawned from a template and endpoint-list. The template resembles an IP SLA configuration minus the targets. The endpoint-list contains only the target information. This is similar to P2P TE Auto-Template (for auto-tunnel meshing) where the single interface spawns many P2P TE tunnels from a single interface. The feature can also be used for dynamic discovery by configuring a responder that can return a list of endpoints to clients requesting it. A use case could include several hundred branch nodes wanting to probe an unknown/constantly changing set of addresses to measure RTT. IP SLA auto-register is not supported on the CSR1000v (version 3.13.2S), despite the IOS-XE 3S documentation clearly stating that it should be. Likewise, creating auto templates is not possible.

```
R2(config)#ip sla responder auto-register AUTOREG
```

```
Auto Register is not supported.
```

```
R1#show ip sla auto template
```

```
[no output]
```

You can create endpoint-lists, which are useless since the feature isn't supported, and the show commands for the "auto" syntax tree do exist. These lists would serve as inputs to the auto-discovery process, assuming it was supported. I document the concept here in case future releases support it.

```

```

IP SLA Two-Way Active Measurement Protocol (TWAMP), an IETF standard protocol, is a way to perform monitoring using another mechanism similar to ordinary IP SLA. Cisco routers can be servers and session-reflectors, but not control-clients or session-senders. The control-clients start and stop sessions, kind of like probing IP SLA devices. The server and control-clients exchange TWAMP-Control messages which are comparable to the IP SLA control packets on UDP ports 1967 (v1) or 1167 (v2). The session-senders send TWAMP-Test (data measurement) packets to session-reflectors, which notify the other session-senders. Servers can accept connections from multiple clients also.

In case you didn't know TWAMP is an IETF protocol, the router reveals the RFC. This command exists to tell you which standards were implemented and which TWAMP roles are supported. This proves the claim earlier that the router is capable of only 2 of the 4 possible TWAMP roles.

```

R2#show ip sla twamp standards

```

Feature	Organization	Standard
TWAMP Server	IETF	RFC5357
TWAMP Reflector	IETF	RFC5357

Below, we configure CSR2 as a TWAMP session-reflector ("responder" command) and a server ("server" command). For TWAMP v1.0, which is the version currently supported, these roles must be on the same device. The following show command shows that you've properly enabled TWAMP as no sessions currently exist. I have not tested TWAMP with a client yet, and since XE and XR don't support that role, it's probably not in scope for the exam.

```

! CSR2
ip sla responder twamp
  timeout 60

ip sla server twamp
  port 60000
  timer inactivity 60

```

```
R2#show ip sla twamp session
IP SLAs Responder TWAMP is: Enabled
```

47.8 Enhanced Object Tracking (EOT)

Enhanced Object Tracking (EOT) is a way for IP SLA results (among other things) to ultimately interact with several unrelated features. For example, a policy-based routing (PB) use-case would include testing reachability to a next-hop. If the next-hop is reachable and fast, send DSCP EF traffic over the link along with DSCP AF11 data flows. If it's reachable but slow, send only data DSCP AF11 over the link. If it's completely down, don't use it at all. IP SLAs can be in one of three non-error states as we discussed earlier: OK, timeout, or over threshold. However, objects can only be up or down. This implies that we need at least two different tracking mechanisms to determine whether or not "over threshold" qualifies as down or not.

We will implement the aforementioned PBR policy as an example. Engineering a test for this in the data-plane is a little tricky. I apply an 8 kbps shaper outbound on CSR1 on a new link to CSR2 (no IGP).

```
! CSR1
policy-map SHAPE_8K
  class class-default
    shape average 8000

interface GigabitEthernet2.521
  encapsulation dot1Q 3521
  ip address 12.0.0.1 255.255.255.0
  service-policy output SHAPE_8K

! CSR2
interface GigabitEthernet3.521
  encapsulation dot1Q 3521
  ip address 12.0.0.2 255.255.255.0
```

I create a probe [ID 170] to test this link using a large packet. I then create a congestion source [IP 171] to send a large packet every second, which is about 12 kbps of traffic. We only care about IP SLA ID 170 and will use that for our EOT testing; IP SLA ID 171 exists purely to create congestion. While this congestion probe is running, the primary probe will alternate between over threshold and timeout, depending.

```
! CSR1
ip sla 170
  icmp-echo 12.0.0.2 source-interface GigabitEthernet2.521
  request-data-size 1450
  threshold 1000
  frequency 5

ip sla 171
  icmp-echo 12.0.0.2 source-interface GigabitEthernet2.521
```

```
request-data-size 1450
threshold 1000
timeout 1000
frequency 1
```

```
ip sla schedule 170 life forever start-time now
ip sla schedule 171 life forever start-time now
```

We create two tracked objects, 10 and 11, that track the state and reachability of our primary probe, respectively. The “state” option is more strict and requires an OK return code (and is the default option), whereas “reachability” is up even if the probe is over threshold. If your probe threshold and timeout are the same value, state and reachability do exactly the same thing from a practical perspective. We can tie these objects into the PBR policy so we can achieve the desired forwarding result.

```
! CSR1
track 10 ip sla 170 state
track 11 ip sla 170 reachability

ip access-list extended ACL_DSCP_EF
 permit ip any any dscp ef

ip access-list extended ACL_DSCP_AF11
 permit ip any any dscp af11

route-map RM_PBR permit 10
 match ip address ACL_DSCP_EF
 set ip next-hop verify-availability 12.0.0.2 10 track 10

route-map RM_PBR permit 20
 match ip address ACL_DSCP_AF11
 set ip next-hop verify-availability 12.0.0.2 10 track 11
```

We apply the route-map globally to CSR1. This affects only locally-generated traffic (be sure to define the ACLs or else the first clause will match everything, breaking many control plane mechanisms).

```
! CSR1
ip local policy route-map RM_PBR
```

First, we will test an uncongested link where both objects should be up and IP SLA ID 171 is not running.

```
R1#show track brief
```

Track	Type	Instance	Parameter	State	Last Change
10	ip sla	170	state	Up	00:01:09
11	ip sla	170	reachability	Up	00:01:09

We will a “voice” probe to generate UDP echoes on port 16384 to CSR2 [ID 172] marked DSCP EF (TOS

184). We also create a “data” probe using TCP with marking DSCP AF11 (TOS 40) [ID 173]. We start both probes together, and we expect both to be policy-routed.

```
! CSR1
ip sla 172
  udp-echo 153.2.2.2 16384
  tos 184
  frequency 5

ip sla 173
  tcp-connect 153.2.2.2 8080
  tos 40
  timeout 5000
  frequency 5

ip sla schedule 172 life forever start-time now
ip sla schedule 173 life forever start-time now
```

Notice that CSR1 marks both the control and data probes (2 packets each) with the specified TOS, and PBR matches both; this is highly desirable as the signaling and bearer traffic will follow the same path. The voice traffic matches “item 10” which is the first route-map entry while the data traffic matches “item 20”. So far, this is indicative of a working configuration.

```
CSR1#debug ip policy
IP: s=153.1.2.1 (local), d=153.2.2.2, len 80, policy match
IP: route map RM_PBR, item 10, permit
IP: s=153.1.2.1 (local), d=153.2.2.2 (GigabitEthernet2.521), len 80, policy
routed
IP: local to GigabitEthernet2.521 12.0.0.2
IP: s=153.1.2.1 (local), d=153.2.2.2, len 44, policy match
IP: route map RM_PBR, item 10, permit
IP: s=153.1.2.1 (local), d=153.2.2.2 (GigabitEthernet2.521), len 44, policy
routed
IP: local to GigabitEthernet2.521 12.0.0.2

IP: s=153.1.2.1 (local), d=153.2.2.2, len 40, policy match
IP: route map RM_PBR, item 20, permit
IP: s=153.1.2.1 (local), d=153.2.2.2 (GigabitEthernet2.521), len 40, policy
routed
IP: local to GigabitEthernet2.521 12.0.0.2
IP: s=153.1.2.1 (local), d=153.2.2.2, len 40, policy match
IP: route map RM_PBR, item 20, permit
IP: s=153.1.2.1 (local), d=153.2.2.2 (GigabitEthernet2.521), len 40, policy
routed
IP: local to GigabitEthernet2.521 12.0.0.2
```

Now we will enable congestion on that link by starting IP SLA ID 171 (not shown). We expect the voice

traffic to not be policy-routed but the data traffic still should be. Track 10 should go down but track 11 should generally stay up. We can see this by looking at the tracked objects, at the route-map directly (in the case of PBR), or implying it from the IP SLA statistics showing failed probes. The “state” is down because the probe is over threshold, but “reachability” is still achievable; the link is “good enough” for data transport.

```
R1#show track brief
```

Track	Type	Instance	Parameter	State	Last Change
10	ip sla	170	state	Down	00:00:09
11	ip sla	170	reachability	Up	00:02:54

```
R1#show route-map RM_PBR
```

```

```

```
ip address (access-lists): ACL_DSCP_AF11
```

```
Set clauses:
```

```
ip next-hop verify-availability 12.0.0.2 10 track 11 [up]
```

```
Policy routing matches: 978 packets, 45398 bytes
```

```
R1#show ip sla statistics 170
```

```
IPSLAs Latest Operation Statistics
```

```
IPSLA operation id: 170
```

```
Latest RTT: 2630 milliseconds
```

```
Latest operation start time: 02:19:21 [snip]
```

```
Latest operation return code: Over threshold
```

```
Number of successes: 388
```

```
Number of failures: 13
```

```
Operation time to live: Forever
```

The voice traffic has the control packet and data packet, both of which were not policy routed. However, we still have policy-routing for item 20 containing the AF11 flow. Notice the debug reveals there was a match in item 10 but the traffic was forwarded normally.

```
! CSR1
```

```
IP: s=153.1.2.1 (local), d=153.2.2.2, len 80, policy match
```

```
IP: route map RM_PBR, item 10, permit
```

```
IP: s=153.1.2.1 (local), d=153.2.2.2, len 80, policy rejected -- normal forwarding
```

```
IP: s=153.1.2.1 (local), d=153.2.2.2, len 80, policy match
```

```
IP: route map RM_PBR, item 20, permit
```

```
IP: s=153.1.2.1 (local), d=153.2.2.2 (GigabitEthernet2.521), len 80, policy
routed
IP: local to GigabitEthernet2.521 12.0.0.2
```

Eliminating reachability altogether is simple; just break the link completely. I will mismatch the VLAN encapsulations to cause this failure (not shown), and expect no traffic to be policy routed. You should not rely on the packet counters of the route-map to determine whether PBR occurs. The counters increase when a match is made, whether routing happens in the route-map clause or not. I prove this by clearing the counters, enabling debug, and watching them increase despite both objects being down. The debug shows a policy match but does not say policy-routed; the two terms are different. Like earlier, we have policy matches but normal forwarding.

```
! CSR1
IP: s=153.1.2.1 (local), d=153.2.2.2, len 80, policy match
IP: route map RM_PBR, item 10, permit
IP: s=153.1.2.1 (local), d=153.2.2.2, len 80, policy rejected -- normal
forwarding
```

```
IP: s=153.1.2.1 (local), d=153.2.2.2, len 40, policy match
IP: route map RM_PBR, item 20, permit
IP: s=153.1.2.1 (local), d=153.2.2.2, len 40, policy rejected -- normal
forwarding
```

```
R1#show route-map RM_PBR | include route-map|matches|avail
route-map RM_PBR, permit, sequence 10
    ip next-hop verify-availability 12.0.0.2 10 track 10 [down]
    Policy routing matches: 168 packets, 5712 bytes
route-map RM_PBR, permit, sequence 20
    ip next-hop verify-availability 12.0.0.2 10 track 11 [down]
    Policy routing matches: 420 packets, 18144 bytes
```

Although not directly related to IP SLA, I will discuss a several other handy features of object tracking. Objects can be grouped together in lists where the state of the list-object is the logical combination of the component objects. The Boolean list is used to combine objects with logical AND, OR, and NOT operations. The list itself is an object which can be used in other places. As an example, we create an object to be up only if objects 10 and 11 are both down. Since both objects 10 and 11 are still down, object 12 should be up.

```
! CSR1
track 12 list boolean and
    object 10 not
    object 11 not
```

```
R1#show track brief
```

Track	Type	Instance	Parameter	State	Last Change
10	ip sla	170	state	Down	00:10:17
11	ip sla	170	reachability	Down	00:10:17

```
12      list                                boolean      Up      00:00:24
```

If I fix the encapsulation error on the link, we expect at least “reachability” to return, which will bring down the new object list. Whether we achieve “state” or not is irrelevant since both objects must be down in order to bring the list up.

```
R1#show track brief
Track Type      Instance      Parameter      State Last Change
10   ip sla     170           state         Up    00:00:14
11   ip sla     170           reachability   Up    00:00:14
12   list                               boolean       Down   00:00:14
```

Interface tracking is one of the simplest forms of tracking. You can track either the interface line-protocol (which is only really valuable for certain link-types, such as serial interfaces) or the IP routing capability. I’ve added a new Loopback1 to CSR1 to test, along with a tracked object to test line-protocol [ID 20] tracking first.

```
! CSR1
interface Loopback1
 ip address 100.1.1.1 255.255.255.255

track 20 interface Loopback1 line-protocol
```

Line-protocol is self-explanatory. When the router sees the interface line-protocol go down, it brings the object down. A unique characteristic of this object is the “carrier-delay” option; this option is configured under an interface which tells the interface how long to delay, after loss of carrier sense, to tell the router the link is down. If the router doesn’t about a failure, it can’t tell EOT to change state, so we have another knob for delay. I’ve set the carrier-delay to 5 seconds on the loopback. Carrier-delay is discussed in greater detail in the layer 1 failure detection section.

```
! CSR1
track 20 interface Loopback1 line-protocol
 carrier-delay

interface Loopback1
 carrier-delay 5
```

To test it, I issue the “show clock” and “shutdown” commands as quickly as I can; we see the difference in time is about 5 seconds between shutting down the Loopback to the time it reports the event.

```
R1(config-if)#do show clock
23:33:14.039 UTC [snip]

R1(config-if)#shutdown

23:33:19: %LINEPROTO-5-UPDOWN: Line protocol on Interface Loopback1, changed
```

state to down

23:33:19: %LINK-5-CHANGED: Interface Loopback1, changed state to administratively down

23:33:19: %TRACK-6-STATE: 20 interface Lo1 line-protocol Up -> Down

Tracking IP routing on a loopback interface is worthless because it will always be down. Cisco states this feature “tracks an IP route in the routing table and the ability of an interface to route IP packets.” Let’s track CSR1’s link to XRv3 instead. The interface is currently up because the interface is up/up and has a valid IP address.

! CSR1

track 21 interface GigabitEthernet2.513 ip routing

This feature is useful for dynamically negotiated addresses (DHCP, IPCP) because it will not come up until the link has a valid IP address. Removing the IP address from the link causes the interface to fail immediately, but we could use various delay mechanisms to tune that (discussed later). Adding the IP interface back brings the object back up.

R1#show track 21 brief

Track	Type	Instance	Parameter	State	Last Change
21	interface	GigabitEthernet2.513	ip routing	Up	00:00:13

! CSR1

interface GigabitEthernet2.513

no ip address

23:38:07: %TRACK-6-STATE: 21 interface Gi2.513 ip routing Up -> Down

! CSR1

interface GigabitEthernet2.513

ip address 153.1.13.1 255.255.255.0

23:38:16: %TRACK-6-STATE: 21 interface Gi2.513 ip routing Down -> Up

Another way to combine items into a list is using thresholds. We will use our knowledge of lists from earlier combined with interface tracking for a simple example [ID 15-18]. We will track three interfaces on CSR1: link to CSR2, link to XRv13, and Loopback1. Tracking line-protocol on Ethernet interfaces isn’t a great indication of link status, but I use it in this demonstration for simplicity. The transit links have a weight of 5, and the loopback has a weight of 10 (the default). We need a total “score” of 15 out of a maximum of 20 for the object to be up, and falling to 10 or less brings the object down.

! CSR1

track 15 list threshold weight

object 16

object 17 weight 5

object 18 weight 5

```
threshold weight down 10 up 15
```

```
track 16 interface Loopback1 line-protocol
track 17 interface GigabitEthernet2.512 line-protocol
track 18 interface GigabitEthernet2.513 line-protocol
```

Given these thresholds, the loopback must be up, and we can afford to lose up to one transit link. The output below first shows the objects all up.

```
R1#show track 15
Track 15
  List threshold weight
  Threshold Weight is Up (20/20)
    2 changes, last change 00:00:23
    object 16 Up (10/20)
    object 17 weight 5 Up (5/20)
    object 18 weight 5 Up (5/20)
  Threshold weight down 10 up 15
```

Next, we shutdown Loopback1. The individual tracker for that loopback goes down along with the overall threshold list.

```
! CSR1
interface Loopback1
  shutdown

23:54:44: %TRACK-6-STATE: 16 interface Lo1 line-protocol Up -> Down
23:54:44: %TRACK-6-STATE: 15 list threshold weight Up -> Down
```

```
R1#show track 15
Track 15
  List threshold weight
  Threshold Weight is Down (10/20)
    3 changes, last change 00:02:47
    object 16 Down (0/20)
    object 17 weight 5 Up (5/20)
    object 18 weight 5 Up (5/20)
  Threshold weight down 10 up 15
```

If we bring the loopback up but shut down a single transit link, the object stays up. In this example, only the link to CSR2 is shutdown.

```
! CSR1
interface Loopback1
  no shutdown

interface GigabitEthernet2.512
  shutdown
```

```

R1#show track 15
Track 15
  List threshold weight
  Threshold Weight is Up (15/20)
    4 changes, last change 00:00:09
    object 16 Up (10/20)
    object 17 weight 5 Down (0/20)
    object 18 weight 5 Up (5/20)
  Threshold weight down 10 up 15

```

We can also do a percentage-based threshold list [ID 19]. All objects have equal weight and you are effectively saying “if some of my objects are up, the list is up”. With three objects, each one is worth 33% and this is not adjustable. I want to ensure at least 2/3 of my tracked interfaces are up. Having 1 or less is a failure condition; this is defined by the up/down threshold percentages. This is a simpler way to do threshold lists without the arithmetic required for weighted lists.

```

! CSR1
track 19 list threshold percentage
  object 16
  object 17
  object 18
  threshold percentage down 33 up 66

```

```

R1#show track 19
Track 19
  List threshold percentage
  Threshold Percentage is Up (100%)
    4 changes, last change 00:01:10
    object 16 Up (33%)
    object 17 Up (33%)
    object 18 Up (33%)
  Threshold percentage down 33% up 66%

```

Because they are weighted equal, I can shut down the loopback1 and have the list still up, assuming I bring up the link to CSR2.

```

! CSR1
interface Loopback1
  shutdown

interface GigabitEthernet2.512
  no shutdown

```

```

R1#show track 19
Track 19
  List threshold percentage
  Threshold Percentage is Up (66%)

```

```
4 changes, last change 00:00:03
object 16 Down (0%)
object 17 Up (33%)
object 18 Up (33%)
Threshold percentage down 33% up 66%
```

The list cannot tolerate the loss of 2 of more links, so the list fails when the loopback1 is also shut down.

```
! CSR1
interface Loopback1
shutdown
```

```
R1#show track 19
Track 19
List threshold percentage
Threshold Percentage is Down (33%)
3 changes, last change 00:00:04
object 16 Down (0%)
object 17 Down (0%)
object 18 Up (33%)
Threshold percentage down 33% up 66%
```

The track resolution feature measures the scaled metric and compares it to a threshold. Let's evaluate the EIGRP default value of 2560. The EIGRP route metric is scaled (divided) by 2560 to account for larger metrics. That is, every change in 2560 counts as 1 in the scaled metric. Example: For a given route, if the scaled metric exceeds 20 (or a true EIGRP metric value of 51200), then the tracked object goes down. When the metric crosses back below 10 (or a true EIGRP metric value of 25600), the object comes back up. Each protocol has a different default scaling value; tuning these values is independent for IPv4 and IPv6 and this feature does not exist in XR. The default scale values for IPv4 and IPv6 are shown below (only IPv4 is shown as the default values are equal for IPv6).

```
R1#show track resolution ip
```

```
IP Route Resolution

Route type      Metric Resolution
static          10
EIGRP           2560
OSPF             1
ISIS            10
BGP             2560
```

Personally, I've used this feature with FHRPs to ensure that if a potential LAN gateway has poor reachability to some key routes (like server farms) that it should relinquish its active role. IP SLA could be used similarly to actively test link quality to those prefixes, but that means loading the network with synthetic traffic. This feature is passive and doesn't require additional network traffic as it just looks at

IGP/BGP route metrics. You could even write an EEM script to generate a syslog or SNMP trap just to notify someone that the event happened, assuming the metric change was significant enough.

We will create a tracked object [ID 25] to track the route to CSR2. Over the direct path, the metric to CSR2's loopback from CSR1 is 130816. Dividing by 2560 and ignoring the remainder, this should result in a scaled metric of 51 (the scaled metric is not known by the RIB and not shown in this output). The object isn't created yet since we need to determine the threshold values.

```
R1#show ip route 153.2.2.2
Routing entry for 153.2.2.2/32
  Known via "eigrp 1", distance 90, metric 130816, type internal
  Redistributing via eigrp 1
  Last update from 153.1.2.2 on GigabitEthernet2.512, 00:00:05 ago
  Routing Descriptor Blocks:
  * 153.1.2.2, from 153.1.2.2, 00:00:05 ago, via GigabitEthernet2.512
    Route metric is 130816, traffic share count is 1
    Total delay is 5010 microseconds, minimum bandwidth is 1000000 Kbit
    Reliability 255/255, minimum MTU 1500 bytes
```

Let's shut down the interface to CSR2. The EIGRP metric via XRv13 is 131328 which is too close (within 2560) to the metric directly via CSR2, which means we either have to reduce the scaling factor or increase the metric to XRv3. We will increase the delay on the link to XRv3 from 10 to 500. Below is the output before the change in delay is applied.

```
R1#show ip route 153.2.2.2
Routing entry for 153.2.2.2/32
  Known via "eigrp 1", distance 90, metric 131328, type internal
  Redistributing via eigrp 1
  Last update from 153.1.13.13 on GigabitEthernet2.513, 20:10:00 ago
  Routing Descriptor Blocks:
  * 153.1.13.13, from 153.1.13.13, 20:10:00 ago, via GigabitEthernet2.513
    Route metric is 131328, traffic share count is 1
    Total delay is 5030 microseconds, minimum bandwidth is 1000000 Kbit
    Reliability 255/255, minimum MTU 1500 bytes
    Loading 1/255, Hops 3
```

The metric via XRv13 is now 259072 with a scaled metric of 101 after the delay change.

```
! CSR1
interface GigabitEthernet2.513
  delay 500
```

```
R1#show ip route 153.2.2.2
Routing entry for 153.2.2.2/32
  Known via "eigrp 1", distance 90, metric 259072, type internal
  Redistributing via eigrp 1
  Last update from 153.1.13.13 on GigabitEthernet2.513, 00:00:05 ago
```

Routing Descriptor Blocks:

```
* 153.1.13.13, from 153.1.13.13, 00:00:05 ago, via GigabitEthernet2.513
  Route metric is 259072, traffic share count is 1
  Total delay is 10020 microseconds, minimum bandwidth is 1000000 Kbit
  Reliability 255/255, minimum MTU 1500 bytes
  Loading 1/255, Hops 3
```

The object can tell us whether we are routing directly via CSR2 or not by tracking the scaled metric as follows. If the value is less than the “up” threshold, the object is up. If the value is greater than the “down” threshold, the object is down. Using thresholds of $x < 55$ and $x > 95$ will work well given the current EIGRP metric configuration.

```
! CSR1
track 25 ip route 153.2.2.2 255.255.255.255 metric threshold
threshold metric up 55 down 95
```

The object is currently down since we are routing via XRv13. The router shows you the RIB and scaled metrics also. This is a good way to double-check your math. Recall that the scaled metric is the RIB metric divided by the scaling factor (2560 for EIGRP by default).

```
R1#show track 25
Track 25
  IP route 153.2.2.2 255.255.255.255 metric threshold
  Metric threshold is Down (EIGRP/259072/101)
    2 changes, last change 00:00:17
  Metric threshold down 95 up 55
  First-hop interface is GigabitEthernet2.513
```

If we bring up the interface to CSR2, the object comes up. When EIGRP converges, the cost to CSR2 is much lower, resulting in a lower scaled metric of 51.

```
R1#show track 25
Track 25
  IP route 153.2.2.2 255.255.255.255 metric threshold
  Metric threshold is Up (EIGRP/130816/51)
    3 changes, last change 00:00:00
  Metric threshold down 95 up 55
  First-hop interface is GigabitEthernet2.512
```

If desired, you can change the scaled metric defaults. Different protocols have different metric ranges. EIGRP and BGP can have very large metrics/MEDs, while OSPF and ISIS tend to use smaller numbers. RIP, for example, is never scaled, and its metrics are translated directly since they only count to 15. Notice that the minimum and maximum limits in the parser are determined by the protocol types.

```
R1(config)#track resolution ip route ospf ?
<1-1562> Resolution value
```

```
R1(config)#track resolution ip route eigrp ?
<256-40000000> Resolution value
```

The “stub-object” is an interesting feature. There are no fancy options involved; you simply create the object, assign a default-state (if desired), and it’s always up or always down. The exception to this, and one of its best use cases, is to have it be controlled by EEM. EEM is discussed in detail in a dedicated section, but a quick example is shown below. A stub-object [ID 30] is created with default state “down” (which is the default, so the configuration does not display it). A manual EEM script can be run which changes it to “up”. You could also use it in conjunction with other tracked objects within track lists.

```
! CSR1
track 30 stub-object

event manager applet SET_30_UP
event none
action 100 track set 30 state up
```

```
R1#show track 30 brief
```

Track	Type	Instance	Parameter	State	Last
Change					
30	stub-object	Undefined		Down	00:01:18

To demonstrate using EEM to adjust the value, we write a small script and manually execute it from the CLI. Assuming some other process relied on this object, we can use EEM to influence network behavior.

```
! CSR1
event manager applet SET_30_UP
event none
action 100 track set 30 state up
```

```
R1#event manager run SET_30_UP
```

```
R1#show track 30 brief
```

Track	Type	Instance	Parameter	State	Last
Change					
30	stub-object	EEM		Up	00:00:02

The track feature also has timers regarding how often it re-evaluates its tracked objects. There are two sets of timers: a global timer which determines how often the router reassesses the state of an object, and a per-object timer which determines how long to delay going up or going down. We will re-use route tracking object 25 from earlier for this demonstration. The default timers are shown below. Notice that some fields say “expired”; this is because there are zero objects of that specified type. We have not configured any IPv6 route objects, which explains this output. The poll interval is measured in seconds and represents the global timer for that object type. The right-most column just counts down to zero, then restarts. Notice that the stub-object, by default, has a fast timer. The route objects have slower timers to allow protocols to converge without flapping object states constantly. If you are using scaled

metric threshold tracking in your environment, the poll interval for IPv4/IPv6 routes should be slightly longer than your IGP convergence time.

```
R1#show track timers
```

```
Tracking Timers
```

Object type	Poll Interval	Time to next poll
interface	1	0.887
ip route	15	12.607
ip sla	5	0.292
ipv6 route	15	expired
list	1	0.67
stub-object	1	0.230

We will enable timestamps on CSR1 and modify the timer to be 30 seconds. You can also set millisecond granularity if desired.

```
! CSR1
service timestamps debug datetime
service timestamps log datetime
track timer ip route 30
```

```
R1#show track timers | include ip_route
ip route          30          12.718
```

The network is fully operational which means the tracked object is up. When the timer restarts at 30 seconds, we will shut down the link to CSR2 on CSR1 immediately thereafter. We expect the tracked object to stay down for about 26-28 seconds or so, depending on how fast I am. The sequence of events is shown below with timestamps and key actions highlighted. The EIGRP neighbor fails immediately as expected, but the tracked object remains in the up state for some time. Notice that the object took 28 seconds to go down, which is what we expected.

```
R1#show track timers | include ip_route
ip route          30          29.887
```

```
! CSR1
interface GigabitEthernet2.512
shutdown
```

```
23:17:28: %DUAL-5-NBRCHANGE: EIGRP-IPv4 1: Neighbor 153.1.2.2
(GigabitEthernet2.512) is down: interface down
```

```
R1#show track timers | include ip_route
ip route          30          0.608
```

```
23:17:56: %TRACK-6-STATE: 25 ip route 153.2.2.2/32 metric threshold Up ->
```

Down

We can also tell the object itself to delay going up or down on a per-object basis. We configure this probe to delay for 10 additional seconds when coming up. We will repeat the same test except we will bring the interface back up, and expect 35-38 seconds of delay (~30 seconds from the track timer plus ~10 seconds from the up-delay). First, we configure the up-delay and verify that the 10 second delay was properly applied to the object.

```
! CSR1
track 25 ip route 153.2.2.2 255.255.255.255 metric threshold
  threshold metric up 55 down 95
  delay up 10

R1#show track 25
Track 25
  IP route 153.2.2.2 255.255.255.255 metric threshold
  Metric threshold is Up (EIGRP/130816/51)
    9 changes, last change 00:13:52
  Metric threshold down 95 up 55
  Delay up 10 secs
  First-hop interface is GigabitEthernet2.512
```

We follow the same test procedure as above except “no shutdown” the link between CSR1 and CSR2. In this case, it was about 36 seconds, since it took EIGRP a few seconds to discover CSR2 and converge. Notice that when the countdown timer hits 0.593 seconds, we still have to wait another 10 seconds because of the per-object delay-up time. In the last example, as soon as the global timer expired, the router re-evaluated the object and changed its state. This time, the router still performed the re-evaluation, directed the object to change state, but the object delayed the “up” action.

```
R1#show track timers | include ip_route
ip route          30          29.626

! CSR1
interface GigabitEthernet2.512
  no shutdown

23:21:00: %DUAL-5-NBRCHANGE: EIGRP-IPv4 1: Neighbor 153.1.2.2
(GigabitEthernet2.512) is up: new adjacency

! About 30 seconds later
R1#show track timers | include ip_route
ip route          30          0.593

! Another 10 seconds later
R1#show track timers | include ip_route
ip route          30          21.441
```

```
23:21:36: %TRACK-6-STATE: 25 ip route 153.2.2.2/32 metric threshold Down ->
Up
```

47.9 IPv6 SLA

A number of probes are supported for IPv6, but not all. Cisco documentation specifies that only ICMP-echo, UDP-echo, UDP-jitter, and TCP-connect are supported, but in reality, the path-echo and path-jitter are also supported (and possibly more). IPv6 SLA operation is identical to that of its IPv4 counterpart. I've configured OSPFv3 using IPv6 AF only (XR doesn't support OSPFv3 AF IPv4) for this demonstration. The configuration is basic and is not shown. The probe numbers used earlier will be repeated but added to 60. For example, IP SLA ID 3 from the IPv4 testing will be ID 63 here.

The first probe to examine is the ICMP-echo probe [ID 61]. The probe has been discussed in detail already so the basic operation is not revisited. Two new options exist under the probe; traffic-class and flow-label. Traffic-class is functionally equivalent to IP TOS and is still an unsigned 8 bit integer. We will use DSCP AF21 for this probe; DSCP AF21 in decimal is 18. Bit-wise left-shifting twice results in a traffic-class value of 72 or 0x48.

```
R1(config-ip-sla-echo)#traffic-class ?
<0-255> Traffic Class Value
```

The flow "label" has nothing to do with MPLS, despite being 20 bits (the exact same size as the label field in the MPLS shim header). This is a component of the IPv6 header with a few key uses. First, it allows routers to avoid having to look deeper into the packet (could be encrypted, etc) to identify the flow. Loosely analogous to the GRE tunnel key with "entropy" enabled, it could be unique per flow to allow for better load-sharing in the core. Packets in the same flow should have the same flow label and should be forwarded along the same path. Intermediate network devices will generally keep packets with the same flow-label in the same path if they have multiple paths to a destination (ECMP, UCMP, etc). In this case, we set a value of 19, but it doesn't do anything significant in the network. A value of zero means the packet has no flow specifications.

```
R1(config-ip-sla-echo)#flow-label ?
<0-1048575> Flow Label Value
```

All other probe configurations (timers, history, scheduling, object tracking) are the same. The probe configuration is shown below for completeness.

```
! CSR1
ip sla 61
 icmp-echo ::153:2:2:2 source-ip ::153:1:1:1
 traffic-class 72
 flow-label 19
 frequency 5
ip sla schedule 61 life forever start-time now
```

We see the probe succeeds without issue. We can also see that our QoS and flow-label settings were properly applied as CSR2's debug reveals those values. The traffic class is shown as a decimal number from 0 to 255 while the flow label is shown in hexadecimal.

```
R1#show ip sla statistics 61 | include Number
Number of successes: 4
Number of failures: 0
```

```
R2#debug ipv6 icmp
IPV6: source ::153:1:1:1 (GigabitEthernet2.512)
      dest ::153:2:2:2 (Loopback0)
      traffic class 72, flow 0x13, len 76+18, prot 58, hops 64, forward to ulp
```

Next, we test the TCP connect probe [ID 62]. Again, the threshold, timeout, and frequency settings work identically for IPv6 as they do for IPv4.

```
! CSR1
ip sla 62
  tcp-connect ::153:2:2:2 55555 source-ip ::153:1:1:1
  threshold 10000
  timeout 10000
  frequency 10
ip sla schedule 62 life forever start-time now
```

We also enable debugging on CSR2, which is a dynamic responder, to ensure the IPv6 TCP operation is successful. Note that "ip sla responder" applies to IPv6 probes without any additional configuration. On an XE responder, the operation 0 must be specified for the debug. Notice that the responder performs the same actions it did for IPv4 and also tracks the IPv6 addressing in its "recent source" list. CSR1 reports no failures.

```
R1#show ip sla statistics 62 | include Number
Number of successes: 5
Number of failures: 0
```

```
R2#debug ip sla trace 0
IPSLA-RESP_TRACE: Receive Control msg: len =68
IPSLA-RESP_TRACE: Ctrl-Msg Ver: 1 ID: 168 Len: 68
IPSLA-RESP_TRACE: Ctrl-Msg: command: SLA_CMD_TCPV6_CONN_ENABLE, ip:
::153:2:2:2, port: 55555, duration: 10000
[snip]
IPSLA-RESP_TRACE: %TRACE: TCP socket accepted
IPSLA-RESP_TRACE: Cleaning up port (::153:2:2:2,55555)
```

```
R2#show ip sla responder
  General IP SLA Responder on Control port 1967
  General IP SLA Responder on Control V2 port 1167
General IP SLA Responder is: Enabled
```

```
Number of control message received: 2 Number of errors: 0
Recent sources:
```

```
::153:1:1:1 [13:53:16.508 UTC DAY MON 11 2015]
::153:1:1:1 [13:53:06.508 UTC DAY MON 11 2015]
```

We also test using a static responder. We configure a probe on CSR2 to send UDP-echoes to CSR1 without any control messaging [ID 63]. This means we need a static responder configured on CSR1 for the target IPv6 address and port pair. The command syntax is the same as it is for IPv4; this is somewhat odd since there is no “ipv6 sla” tree, yet the IPv6 functionality is nested within the “ip sla” tree.

```
! CSR1
ip sla responder udp-echo ipaddress ::153:1:1:1 port 55556
```

```
R1#show ip sla responder | section udp
udpEcho Responder:
```

IP Address	Port
153.1.1.1	55556
153.1.1.1	55557
::153:1:1:1	55556

Next, we configure the probe on CSR2. As expected, no failures are observed since CSR1 is responding properly to these probes.

```
! CSR2
ip sla 63
  udp-echo ::153:1:1:1 55556 control disable
  frequency 5
ip sla schedule 63 life forever start-time now
```

```
R2#show ip sla statistics 63 | include Number
Number of successes: 3
Number of failures: 0
```

Recall that UDP-jitter was a complicated operation because the information it is capable of resolving is dependent upon a few things. First, NTP synchronization determines whether the probe resolves one-way latency or not. Second, a dynamic responder is required for jitter/MOS resolution. We quickly verify these behaviors with IPv6 SLA. We create a UDP-jitter probe on CSR2 with control-messages disabled to probe CSR1 [ID 64]. With NTP configured, we expect to resolve one-way latency only. For consistency, we will use the same parameters as IP SLA ID 4, to include the port number, which means we need to quickly add another static responder entry to CSR1 (not shown).

```
! CSR2
ip sla 64
  udp-jitter ::153:1:1:1 55557 control disable num-packets 200 interval 25
  request-data-size 72
  frequency 10
```

```
ip sla schedule 64 life forever start-time now
```

```
R2#show ntp status | include ^sync
```

```
Clock is synchronized, stratum 9, reference is 153.1.1.1
```

```
R2#show ip sla statistics 64 | section Latency|Jitter|Number
```

```

```

```
Destination to Source Loss Periods Number: 0
```

```
Number of successes: 7
```

```
Number of failures: 0
```

Trying a similar probe in the opposite direction from CSR1 to CSR2 [ID 65], we get statistics for jitter and latency. This is because NTP is synchronized and CSR2 is already a dynamic IP SLA responder.

```
! CSR1
```

```
ip sla 65
```

```
udp-jitter ::153:2:2:2 55558 num-packets 200 interval 25
```

```
request-data-size 72
```

```
frequency 10
```

Note that if the latency is very low, the router may just display all zeroes, even for the number of samples. To increase latency a little, I shut down the direct link between CSR1 and CSR2. The reason we know that this was not occurring for IP SLA ID 64 is because the number of jitter samples was still zero.

```
R1#show ip sla statistics 65 | section Jitter|Latency|Number
```

```
Number Of RTT: 200 RTT Min/Avg/Max: 3/4/66 milliseconds
```

```
Latency one-way time:
```

```

```

```
Number Of RTT Over Threshold: 0 (0%)
```

```
Source to Destination Loss Periods Number: 0
```

```
Destination to Source Loss Periods Number: 0
Number of successes: 33
Number of failures: 0
```

Advanced ICMP probes, such as path-echo and path-jitter, also appear supported. The path-echo probe configured on CSR1 to test IPv6 [ID 70] mirrors the configuration of its IPv4 counterpart.

```
! CSR1
ip sla 70
  path-echo ::153:2:2:2
  threshold 50
  timeout 100
  frequency 10
  hops-of-statistics-kept 3
  samples-of-history-kept 10
ip sla schedule 70 life forever start-time now
```

Remember that in order to see valuable data from this probe, we need to look at the aggregated statistics. This particular probe discovers each of the hops in each of the paths (2 dimensional array, or matrix of values) and displays them within the aggregated statistics.

```
R1#show ip sla statistics aggregated 70
IPSLAs aggregated statistics

IPSLA operation id: 70

Number of failures: 0
Target Address ::153:2:2:2
```

Last, we examine path-jitter for IPv6. Recall that this probe discovers all hops as returned by “traceroute”, which runs first. Then, individual prober operations are spawned to measure metrics for each hop. As such, we must have reachability to the transit links (unless IPv6 LL addressing is used), so OSPFv3 prefix-suppression should not be enabled. In this case, the loopback on each device is the only routable IPv6 address, and as such, is used as the source address for all ICMP unreachables returned to CSR1. If the transit links had any other addressing, the probing device would need reachability to whatever “traceroute” returns. The path-jitter probe configured on CSR1 [ID 71] will trace the path to CSR2, and the direct link to CSR2 is still down. We can see the output is very similar to IPv4.

```
! CSR1
ip sla 71
  path-jitter ::153:2:2:2 source-ip ::153:1:1:1
  frequency 5
ip sla schedule 71 life forever start-time now

It is likely that the DNS, HTTP, and FTP probes work for IPv6 also, but they are not tested here for brevity. The MPLS ones only work for IPv4 FECs current. DHCP does not appear to support IPv6, which makes sense since the DHCPv4 and DHCPv6 operations are fundamentally different (address vs. prefix).

47.10 IOS-XR IP SLA and EOT

IOS XR IP SLA is not very different from IOS and XE. A few quick notes:

1. TCP-connect and fancy operations (HTTP, DNS, HTTP, DHCP, etc) are not supported.
2. ICMP operations supported include echo, path-echo, and path-jitter. No ICMP-jitter.
3. UDP operations supported include echo and jitter. VOIP-style codec probes are not supported.
4. MPLS operations supported include ping and traceroute for both IPv4 and TE targets.
5. In general, XR is less capable than XE with regards to IP SLA.

Because TCP operations are not supported, all static IP SLA responders only give the option for UDP, and only IPv4 responders appear to be supported also. We will quick iterate over the list of probes already discussed. XRv4 is configured as a dynamic IP SLA responder. The IDs of each re-tested probe will have an ID of 300 plus whatever number the original probe was on CSR1 or CSR2.

```
! XRv4
ipsla
  responder
```

The first test is the basic ICMP-echo probe. We will configure it from XRv3 to XRv4 [ID 301].

```
! XRv3
ipsla
  operation 301
  type icmp echo
  source address 153.13.13.13
  destination address 153.14.14.14
  frequency 5

  schedule operation 301
  start-time now
  life forever
```

We can see the probe is successful and it provides a detailed RTT breakdown also, unlike IOS and XE. Quick tip: You can un-schedule all probes at once with “no ipsla schedule”.

```
RP/0/0/CPU0:XRv3#show ipsla statistics 301
Entry number: 301
```

```

```

IOS XR has a different way of indicating failures. The output below clearly shows the number of attempts, but then has some Boolean variables representing whether the operation timed out or connection was lost. Since ICMP is connectionless, this field doesn't apply, but once XRv4's loopback is shutdown, the IP SLA process marks the timeout flag as TRUE and increments the "skipped" counter. This isn't a great description because the operation wasn't skipped; it did run, but it failed. The XE mechanism of reporting successes/failures was more straightforward.

```

RP/0/0/CPU0:XRv3#show ipsla statistics 301
Entry number: 301
[snip]
Number of operations attempted: 10
Number of operations skipped  : 1
Current seconds left in Life  : Forever
Operational state of entry    : Active
Operational frequency(seconds): 5
Connection loss occurred      : FALSE
Timeout occurred              : TRUE
[snip]

```

Next, we will configure a path-echo probe in the same direction [ID 310]. I have shutdown XRv3's link to XRv4 to force traffic through CSR1 and CSR2.

```

! XRv3
ipsla
 operation 310
  type icmp path-echo
  source address 153.13.13.13
  destination address 153.14.14.14
  frequency 10

 schedule operation 301

```

```
start-time now
life forever
```

Traceroute quickly reveals the effect of this minor routing change.

```
RP/0/0/CPU0:XRv3#traceroute 153.14.14.14 source 153.13.13.13
```

```
Type escape sequence to abort.
Tracing the route to 153.14.14.14
```

```
 1  153.1.13.1 [MPLS: Label 1004 Exp 0] 0 msec  0 msec  0 msec
 2  153.1.2.2 [MPLS: Label 2004 Exp 0] 0 msec  0 msec  0 msec
 3  153.2.14.14 0 msec  *  0 msec
```

Next, I disable ICMP unreachable on XRv4's interface facing CSR2, causing traceroute to fail.

```
! XRv4
interface GigabitEthernet0/0/0/0.524
  ipv4 unreachable disable
```

```
RP/0/0/CPU0:XRv3#traceroute 153.14.14.14 source 153.13.13.13
```

```
Type escape sequence to abort.
Tracing the route to 153.14.14.14
```

```
 1  153.1.13.1 [MPLS: Label 1004 Exp 0] 0 msec  0 msec  0 msec
 2  153.1.2.2 [MPLS: Label 2004 Exp 0] 0 msec  0 msec  0 msec
 3  * * *
[snip]
```

Unfortunately, we can't see much in XR because the debugs are not helpful; they are all marked with "cisco-support", so Cisco did not intend for the general user to rely on them. The good news is that the show command actually does report failures and timeouts at least for this probe type, unlike IOS and XE.

```
RP/0/0/CPU0:XRv3#debug ipsla ?
```

```
common      Debug the IPSLA common modules(cisco-support)
error        Output IP SLAs Error Messages(cisco-support)
ippmserver   Debug the IPSLA IPPM Server process(cisco-support)
master-agent Debug the IPSLA master agent process(cisco-support)
responder    Debug the IPSLA responder process(cisco-support)
sub-agent    Debug the IPSLA sub agent process(cisco-support)
trace        Output IP SLAs Trace Messages(cisco-support)
```

```
RP/0/0/CPU0:XRv3#show ipsla statistics 310
```

```
Entry number: 310
```

```
[snip]
```

```
Number of operations attempted: 8
```

```
Number of operations skipped : 24
```

```

Current seconds left in Life : Forever
Operational state of entry   : Active
Operational frequency(seconds): 10
Connection loss occurred     : FALSE
Timeout occurred             : TRUE
[snip]

```

Once we rollback the change on XRv4 to allow it to send unreachable again (not shown), we see the timeout value change to false and the “attempted” operations begins to increase again.

```

RP/0/0/CPU0:XRv3#show ipsla statistics 310
Entry number: 310
[snip]
Number of operations attempted: 12
Number of operations skipped   : 32
Current seconds left in Life   : Forever
Operational state of entry     : Active
Operational frequency(seconds): 10
Connection loss occurred       : FALSE
Timeout occurred               : FALSE
[snip]

```

Next is the path-jitter which is configured on XRv3 [ID 312]. This operation issues a traceroute first, follow by ICMP-echo probes to each hop returned within the traceroute list. We still have the same variables from before: N, S, T, and F. I’ve included their default values where known.

```

RP/0/0/CPU0:XRv3(config-ipsla-op)#type icmp path-jitter ?
count      Number of packets to be transmitted during a probe ! (N, 10 pkts)
interval    Inter packet interval ! (T, 20 msec)

```

```

RP/0/0/CPU0:XRv3(config-ipsla-op)#type icmp path-jitter ?
datasize    Protocol data size in payload of probe packets ! (S)
frequency    Frequency of the probing ! (F, 60 sec)

```

```

! XRv3
ipsla
operation 312
type icmp path-jitter
source address 153.13.13.13
destination address 153.14.14.14
frequency 10

schedule operation 312
start-time now
life forever

```

We start the probe and then check the statistics. We expect to see three hops in the path (CSR1, CSR2,

and XRv4). The output from XR is very extensive but provides similar information as IOS and XE. I have omitted the statistical output from subsequent hops but it is present for the first hop. There does not appear to be way to specify "targetOnly" as we did in IOS and XE, but this is a minor feature anyway.

```
RP/0/0/CPU0:XRv3#show ipsla statistics 312
```

```
Entry number: 312
```

Next, we will configure a UDP-echo on XRv4 to probe XRv3's loopback [ID 303]. We will make XRv3 a static responder for UDP 55556 and the IP address of its loopback (which is the address XRv4 is targeting). Control-messages should be disabled on XRv4 as the UDP data should be sent immediately.

```
! XRv3
ipsla
  responder
    type udp ipv4 address 153.13.13.13 port 55556

! XRv4
ipsla
  operation 303
    type udp echo
    source address 153.14.14.14
    destination address 153.13.13.13
    control disable
    destination port 55556

schedule operation 303
  start-time now
  life forever
```

XRv4 reports success and XRv3, as a static responder, also counts the received probes on that specific port/address pair. Notice there are no control probes on a static (aka permanent) responder.

```
RP/0/0/CPU0:XRv4#show ipsla statistics 303
```

```
Entry number: 303
```

[snip]

```

Operational frequency(seconds): 60
Connection loss occurred      : FALSE
Timeout occurred               : FALSE
Latest RTT (milliseconds)     : 1
[snip]
```

```
RP/0/0/CPU0:XRv3#show ipsla responder statistics all ports
```

```
Port Statistics
```

Local Address	Port	Port Type	Probes	Drops	CtrlProbes	Discard
153.13.13.13	55556	Permanent	2	0	0	

Next we will examine the UDP-jitter probe on XR. This was an interesting probe with many contributing

factors beyond the scope of the probe itself. We will configure a probe on XRv4 [ID 304] to probe XRv3's loopback for latency/jitter information. Notice we use the same UDP destination port of 55556 which already has a corresponding static responder configured on XRv3 from the last example.

```
! XRv4
ipsla
  operation 304
    type udp jitter
    source address 153.14.14.14
    destination address 153.13.13.13
    control disable
    destination port 55556
    frequency 10

  schedule operation 304
    start-time now
    life forever
```

The two routers are not synchronized with NTP and the responder is static. As expected, we cannot resolve jitter or one-way delay (latency). So far, this is consistent with IOS and XE behaviors.

```
RP/0/0/CPU0:XRv4#show ipsla statistics 304
Entry number: 304
  [snip]
  Number of operations attempted: 5
  Number of operations skipped   : 0
  Current seconds left in Life   : Forever
  Operational state of entry     : Active
  Operational frequency(seconds): 10
  Connection loss occurred       : FALSE
  Timeout occurred               : FALSE
  [snip]
  Latest operation return code   : OK
  RTT Values:
    RTTAvg   : 1           RTTMin: 1           RTTMax : 1
    NumOfRTT: 10          RTTSum: 10          RTTSum2: 10
  Packet Loss Values:
    [snip]
  Jitter Values :
    MinOfPositivesSD: 0           MaxOfPositivesSD: 0
    NumOfPositivesSD: 0           SumOfPositivesSD: 0
    Sum2PositivesSD : 0
    MinOfNegativesSD: 0           MaxOfNegativesSD: 0
    [snip]
  One Way Values :
    NumOfOW: 0
    OWMinSD : 0           OWMaxSD: 0           OWSumSD: 0
    OWSum2SD: 0           OWAveSD: 0
```

```
OWMinDS : 0          OWMaxDS: 0          OWSumDS: 0
OWSum2DS: 0         OWAveDS: 0
```

Configuring another UDP jitter probe on XRv3 to probe XRv4 will use XRv4's dynamic responder and should give us jitter, but not latency [ID 305].

```
! XRv3
ipsla
  operation 305
    type udp jitter
    source address 153.13.13.13
    destination address 153.14.14.14
    destination port 55558

schedule operation 305
  start-time now
  life forever
```

As expected, IP SLA ID 305 can resolve jitter only as a result of XRv4 being a dynamic responder. The lack of NTP synchronization implies that one-way latency cannot be collected.

```
RP/0/0/CPU0:XRv3#show ipsla statistics 305
Entry number: 305
[snip]
Number of operations attempted: 2
Number of operations skipped : 0
Current seconds left in Life : Forever
Operational state of entry : Active
Operational frequency(seconds): 60
Connection loss occurred : FALSE
Timeout occurred : FALSE
[snip]
Latest operation return code : OK
[snip]
Jitter Values :
  MinOfPositivesSD: 40          MaxOfPositivesSD: 40
  NumOfPositivesSD: 1          SumOfPositivesSD: 40
  Sum2PositivesSD : 1600
[snip]
JitterAve: 40          JitterSDAve: 40          JitterDSAve: 0
Interarrival jitterout: 0          Interarrival jitterin: 0
One Way Values :
  NumOfOW: 0
  OWMinSD : 0          OWMaxSD: 0          OWSumSD: 0
  OWSum2SD: 0          OWAveSD: 0
  OWMinDS : 0          OWMaxDS: 0          OWSumDS: 0
  OWSum2DS: 0          OWAveDS: 0
```

Notice how the responder on XRv4 records this as a dynamically-learned probe and tracks its progress. The responder also shows that control probes were received, which makes sense for a dynamic responder.

```
RP/0/0/CPU0:XRv4#show ipsla responder statistics all ports
Port Statistics
-----
Local Address   Port  Port Type  Probes    Drops    CtrlProbes Discard
153.14.14.14    55558 Dynamic    20         0         2         ON
```

Let's quickly enable NTP on the XRv routers, using CSR1 as the server because it's already configured for it. We wait several minutes for NTP to synchronize.

```
! XRv3 and XRv4
ntp
server 153.1.1.1 source Loopback0
```

```
RP/0/0/CPU0:XRv3#show ntp status | include sync
Clock is synchronized, stratum 9, reference is 153.1.1.1
```

```
RP/0/0/CPU0:XRv4#show ntp status | include sync
Clock is synchronized, stratum 9, reference is 153.1.1.1
```

IP SLA ID 305 on XRv3 should start reporting both latency and jitter since it is targeting a dynamic responder. IP SLA ID 304 on XRv4 should start reporting latency only since it is targeting a static responder. The only change we made in the network was synchronizing time; this proves that the XR behavior is identical to IOS and XE with respect to latency and jitter resolution/collection.

```
RP/0/0/CPU0:XRv3# show ipsla statistics 305
Entry number: 305
[snip]

```

Next, we will examine the MPLS ping and traceroute operations. Remember that “mpls oam” must be explicitly enabled in order to use these commands; this is not enabled by default in XR. We will configure an MPLS LSP ping [ID 313] and LSP traceroute [ID 314] on XRv3 targeting XRv4’s loopback address. Before configuring the probes, we will manually test MPLS ping/traceroute from the CLI. Everything looks correct so far.

```
RP/0/0/CPU0:XRv3#ping mpls ipv4 153.14.14.14/32 source 153.13.13.13
```

```
[snip]
```

```
!!!!!
```

```
Success rate is 100 percent (5/5), round-trip min/avg/max = 1/2/10 ms
```

```
RP/0/0/CPU0:XRv3#trace mpls ipv4 153.14.14.14/32 source 153.13.13.13
```

```
[snip]
```

```
Codes: '!' - success, 'Q' - request not sent, '.' - timeout,
       'L' - labeled output interface, 'B' - unlabeled output interface,
```

```
[snip]
```

```
Type escape sequence to abort.
```

```

0 153.1.13.13 MRU 1500 [Labels: 1004 Exp: 0]
L 1 153.1.13.1 MRU 1500 [Labels: 2004 Exp: 0] 0 ms
L 2 153.1.2.2 MRU 1500 [Labels: implicit-null Exp: 0] 10 ms
! 3 153.2.14.14 1 ms

```

Next, we configure the probes. It is interesting to note that sometimes exp-null is required to get XR to respond to MPLS OAM traceroute probes. This is true when XR is the target of an LSP traceroute, but isn’t terribly significant since XR IP SLA supports it. Notice that the configuration between the LSP ping and traceroute operations is identical since the features share many common parameters and

behaviors.

```
! XRv3
ipsla
  operation 313
    type mpls lsp ping
    source address 153.13.13.13
    target ipv4 153.14.14.14/32
    frequency 10
    force explicit-null

  operation 314
    type mpls lsp trace
    source address 153.13.13.13
    target ipv4 153.14.14.14/32
    frequency 10
    force explicit-null

  schedule operation 313
    start-time now
    life forever

  schedule operation 314
    start-time now
    life forever
```

Checking the probe statistics, everything appears to be working. This makes sense since we manually tested the LSP ping/traceroute operations before configuring the probes.

```
RP/0/0/CPU0:XRv3#show ipsla statistics 313 | utility egrep
'Number|Timeout|loss'
  Number of operations attempted: 6
  Number of operations skipped   : 0
  Connection loss occurred       : FALSE
  Timeout occurred               : FALSE

RP/0/0/CPU0:XRv3#show ipsla statistics 314 | utility egrep
'Number|Timeout|loss'
  Number of operations attempted: 4
  Number of operations skipped   : 0
  Connection loss occurred       : FALSE
  Timeout occurred               : FALSE
```

We will temporarily break the LSP by telling CSR2 to stop advertising LDP labels completely. We will rerun our manual verifications and expect the probes to report failures also. XRv did not increase the “skipped” counter for the MPLS ping failures, but instead said connection loss occurred. The MPLS traceroute doesn’t change the timeout/connection flags nor does it increment the “skipped” counter; it only reports the RTT as unknown, so you can use that as a measurement. This can be difficult to identify

when looking at the outputs quickly.

```
! CSR2
no mpls ldp advertise-labels

RP/0/0/CPU0:XRv3#ping mpls ipv4 153.14.14.14/32 source 153.13.13.13
[snip]
Codes: '!' - success, 'Q' - request not sent, '.' - timeout,
       'L' - labeled output interface, 'B' - unlabeled output interface,
[snip]
BBBBB
Success rate is 0 percent (0/5)

RP/0/0/CPU0:XRv3#traceroute mpls ipv4 153.14.14.14/32 source 153.13.13.13
[snip]
Codes: '!' - success, 'Q' - request not sent, '.' - timeout,
       'L' - labeled output interface, 'B' - unlabeled output interface,
[snip]

  0 153.1.13.13 MRU 1500 [Labels: 1004 Exp: 0]
B 1 153.1.13.1 MRU 1500 [No Label] 0 ms

RP/0/0/CPU0:XRv3#show ipsla statistics 313 | utility egrep
'Number|Timeout|loss'
    Number of operations attempted: 50
    Number of operations skipped   : 0
    Connection loss occurred       : TRUE
    Timeout occurred               : FALSE

RP/0/0/CPU0:XRv3#show ipsla statistics 314 | utility egrep
'Number|Timeout|loss|Latest RTT'
    Number of operations attempted: 55
    Number of operations skipped   : 0
    Connection loss occurred       : FALSE
    Timeout occurred               : FALSE
    Latest RTT (milliseconds)     : Unknown
```

To see some extra valuable information on the MPLS traceroute, be sure to use the aggregated statistics show command. Unfortunately, unlike XE, this does not show the LSP hop-by-hop. The detail modifier prints the output in a compact tabular format shown below.

```
RP/0/0/CPU0:XRv3#show ipsla statistics aggregated detail 314 | begin ^Entry S
Entry StartT      Pth Hop Dst Comps   SumCmp  SumCmp2H  SumCmp2L  TMax  TMin
314   1436637790389 0   0  0   22    22      0      22      1    1
314   1436638019453 0   0  0   17    17      0      17      1    1
```

The MPLS ping and traceroute features can also test a TE tunnel. Be careful if you are using XRv 5.3.0 with verbatim TE; bug CSCus55972 states that the next hop in the ERO path must be a /32, so XRv3 has a static route to 153.1.13.1/32. The connected /24 is not good enough for TE tunnel construction as a result. Using a static route is Cisco's suggested workaround. This is totally unrelated to IP SLA but I mention it here to explain why the static route is configured. The only reason we use verbatim path-options is to build TE tunnels over EIGRP as the IGP as it is incapable of carrying TE topology information.

```

  L 2 153.1.2.2 MRU 1500 [Labels: implicit-null Exp: 0] 0 ms
  ! 3 153.2.14.14 1 ms
```

We will configure a ping probe [ID 370] and a traceroute probe [ID 371] on XRv3 to test the state of this tunnel at regular intervals (every 10 seconds).

```

! XRv3
ipsla
  operation 370
    type mpls lsp ping
    target traffic-eng tunnel 34
    frequency 10

  operation 371
    type mpls lsp trace
    target traffic-eng tunnel 34
    frequency 10

schedule operation 370
  start-time now
  life forever

schedule operation 371
  start-time now
  life forever

```

Below are the outputs from probes; both are successful.

```
RP/0/0/CPU0:XRv3#show ipsla statistics 370 | utility egrep
```

```

'Number|loss|return code|Latest RTT'
  Number of operations attempted: 2
  Number of operations skipped   : 0
  Connection loss occurred       : FALSE
  Latest RTT (milliseconds)      : 1
  Latest operation return code   : OK

```

```
RP/0/0/CPU0:XRv3#show ipsla statistics 371 | utility egrep
```

```

'Number|loss|return code'
  Number of operations attempted: 3
  Number of operations skipped   : 0
  Connection loss occurred       : FALSE
  Latest operation return code   : OK

```

To simulate a failure, we will disable MPLS TE tunnels globally on CSR2. This rips out the RSVP-based LSP and sends a PATHERR message back to the headend. We would expect the tunnel to be dysfunctional now. In fact, the MPLS OAM process doesn't even send the pings because the tunnel is down.

```

! CSR2
no mpls traffic-eng tunnels

```

Below are the failed probes. These outputs are more consistent than the IPv4 MPLS ping/traceroute manual tests shown above. They both continue to increment the “attempted” counter, but both indicate connection loss and tell us there was a TX error along the LSP. The output above indicates the requests were not even sent because the LSP is down entirely. This output is very clear and concise, even more so than the XE equivalent.

```

RP/0/0/CPU0:XRv3#show ipsla statistics 370 | utility egrep

  Connection loss occurred       : TRUE
  Latest operation return code   : MplsLspEchoTxError
```

XR simplifies the configuration logic for aggregation statics and history. There are two different syntax trees now: history and statistics. We will reuse IP SLA ID 301 to test these features and attempt to mirror the settings from IP SLA ID 1 on CSR1. The original goal was to collect aggregate statistics for RTT in “buckets” of width 25 ms between 0 and 100 (so we need 4 buckets). We also want to collect history for all events (not just failures) in a rotating list with 15 buckets. XR does not give us an option on how often to sample for history, probably because it writes history in step with the probe frequency (which makes sense). The configuration is shown below. Be sure to modify the “statistics hourly” category since the statistics “interval” is measured only in seconds. The hourly aggregated statistics is where we achieve the granularity we expect. The “statistics interval” is used for collecting enhanced statistics which is shown later.

```

! XRv3
ipsla
operation 301
type icmp echo
  history
  lives 1
  filter all
  buckets 15

source address 153.13.13.13
destination address 153.14.14.14
statistics hourly
  buckets 1
  distribution count 4
  distribution interval 25

frequency 5
statistics interval 5
  buckets 4

```

The output doesn't show us the bucket breakdowns like XE did, but we know each row is a bucket of width 25ms. All of our probes are landing in the first bucket since the network is small and RTT is low.

```

RP/0/0/CPU0:XRv3#show ipsla statistics aggregated detail 301 | begin Entry S
Entry StartT      Pth Hop Dst Comps  SumCmp  SumCmp2H  SumCmp2L  TMax  TMin
301  1436638963658 1   1   0   10     10      0       10      1     1
301  1436638963658 1   1   1   0      0      0       0       0     0
301  1436638963658 1   1   2   0      0      0       0       0     0
301  1436638963658 1   1   3   0      0      0       0       0     0

```

We can also view enhanced statistics which is based on the interval we configured earlier. Every 5 seconds, the router computes these statistics for display. This shows enhanced failure statistics over time.

```

RP/0/0/CPU0:XRv3#show ipsla statistics enhanced aggregated 301

      Bucket : 2
[snip]
```

Without examining every case, we will briefly examine IP SLA reaction configurations. In this example, we will configure XRv3 to issue a syslog message and start a path-echo operation [ID 312] if XRv4's loopback becomes unreachable after 3 consecutive failures of the ICMP-echo operation [ID 301]. The path-echo should only run for 5 minutes (300 seconds) when invoked. The configuration is rather involved, just like XE, and is shown below. The key command is "reaction trigger" which effectively says "if probe 301 experiences the trigger condition, start probe 312".

```
! XRv3
ipsla
  reaction operation 301
    react timeout
    action logging
    action trigger
    threshold type consecutive 3

  reaction trigger 301 312

  schedule operation 301
    start-time now
    life forever

  schedule operation 312
    start-time pending
    life 300
```

Initially, the ICMP-echo probe succeeds and the path-echo is not yet running, as expected.

```
RP/0/0/CPU0:XRv3#show ipsla statistics 301 | utility egrep 'Number|occurred'
  Number of operations attempted: 6
  Number of operations skipped   : 0
  Connection loss occurred       : FALSE
  Timeout occurred               : FALSE

RP/0/0/CPU0:XRv3#show ipsla statistics 312
Entry number: 312
  Modification time: 18:58:55.476 UTC [snip]
  Start time       : Not started yet
[snip]
```

If we temporarily apply an ACL to CSR1 that denies all ICMP echoes, we expect it see XRv3 log the event and start the path-echo probe after 3 consecutive failures. I will temporarily remove LDP from CSR1's interface to XRv3 so that traffic is raw IP, otherwise the ACL cannot classify it. Below is the syslog

message, failures from the original probe, and the starting of the second probe. The second probe fails too because it is ICMP-based but it doesn't matter for this test. I was just illustrating the reaction configuration to ensure that second probe was started at the proper time.

```
! CSR1
ip access-list extended ACL_DENY_ICMP_ECHO
  deny  icmp any any echo
  permit ip any any

interface GigabitEthernet2.513
  ip access-group ACL_DENY_ICMP_ECHO in
  no mpls ip

! XRv3
ipsla_sa[260]: %MGBL-IPSLA-5-THRESHOLD_SET : Monitor element has exceeded the
threshold condition. Op:301, TargetAddr:153.14.14.14,
MonElem:Timeout (Type:consecutive)

RP/0/0/CPU0:XRv3#show ipsla statistics 301 | utility egrep 'Number|occurred'
  Number of operations attempted: 9
  Number of operations skipped   : 9
  Connection loss occurred      : FALSE
  Timeout occurred              : TRUE

RP/0/0/CPU0:XRv3#show ipsla statistics 312 | utility egrep 'Number|occurred'
  Number of operations attempted: 11
  Number of operations skipped   : 0
  Connection loss occurred      : FALSE
  Timeout occurred              : TRUE
```

When I re-enabled MPLS on the link, the traffic succeeds as it tunnels through CSR1 so the ACL does nothing. Notice this log message says “threshold clear” and “reset”, while the first one said “threshold set” and “exceeded”. I also remove the ACL for cleanup purposes.

```
! CSR1
interface GigabitEthernet2.513
  no ip access-group ACL_DENY_ICMP_ECHO in
  mpls ip

! XRv3
ipsla_sa[260]: %MGBL-IPSLA-5-THRESHOLD_CLEAR : Monitor element has reset the
threshold reaction. Op:301, TargetAddr:153.14.14.14,

RP/0/0/CPU0:XRv3#show ipsla statistics 301 | utility egrep 'Number|occurred'
  Number of operations attempted: 76
  Number of operations skipped   : 17
```

```
Connection loss occurred      : FALSE
Timeout occurred             : FALSE
```

TWAMP was discussed earlier but in the context of XR the feature set is identical; only the server and session-reflector are supported in XR. Like XE, “server” enables TWAMP server and “responder” enables TWAMP session-reflector, which for v1.0 must be on the same router. Also like XE, we can see the TWAMP standards for reference; this is useful when determining interoperability between different platforms or vendors.

```
! XRv4
ipsla
  server twamp
  port 60000
```

```
  responder
  twamp
```

```
RP/0/0/CPU0:XRv4#show ipsla twamp status
```

```
TWAMP Server is enabled
```

```
TWAMP Server port : 60000
```

```
TWAMP Reflector is enabled
```

```
RP/0/0/CPU0:XRv4#show ipsla twamp standards
```

Feature	Organization	Standard
TWAMP Server	IETF	RFC5357
TWAMP Reflector	IETF	RFC5357

Now we will examine the IPv6 SLA probes supported in XR. Their behavior is generally identical to their IPv4 counterparts, as we saw in XE also. We begin with the IPv6 ICMP-echo probe [ID 361] on XRv3. XR still calls the IPv6 “TOS” as opposed to the more correct “traffic-class”. There does not appear to be an option for assigning flow-labels at this time, either. This is probably a result of sharing the same syntax tree as IPv4 rather than being subcomponents of a probe-type as seen in XE.

```
! XRv3
operation 361
  type icmp echo
  source address ::153:13:13:13
  destination address ::153:14:14:14
  frequency 5

schedule operation 301
  start-time now
  life forever
```

We schedule the probe to ping XRv4’s loopback and see no issues.

```
RP/0/0/CPU0:XRv3#show ipsla statistics 361 | utility egrep 'Number|occurred'
```

```
Number of operations attempted: 7
Number of operations skipped   : 0
Connection loss occurred      : FALSE
Timeout occurred              : FALSE
```

None of the UDP probes appear to support IPv6 in XR v5.3.0. As such, they are not discussed further.

```
RP/0/0/CPU0:XRv4(config-ipsla-op)#type udp echo destination address ?
A.B.C.D Enter IPv4 address of the target device
```

```
RP/0/0/CPU0:XRv4(config-ipsla-op)#type udp jitter destination address ?
A.B.C.D Enter IPv4 address of the target device
```

Enhanced Object Tracking (EOT) is similar in XR as in IOS/XE. One enhancement is the ability to use named objects, not just numbers. However, XR only supports a limited number of objects: rtr (ip sla), ipv4 route (not IPv6), list, and line-protocol. We will quickly test these options using some dummy objects as their functions are identical to what was already tested and documented. There does not appear a way to set an object's default state. My workaround for this is to use the line-protocol object; to have an always-up object, track a loopback interface. To have an always-down object, track a non-existent interface. Below is the verification of my basic TRUE/FALSE objects; these are like stub-objects in a sense but cannot have their states changed by EEM.

```
! XRv3
track ALWAYS_TRUE
type line-protocol state
interface Loopback0
```

```
track ALWAYS_FALSE
type line-protocol state
interface Loopback999
```

```
RP/0/0/CPU0:XRv3#show track brief
```

Track	Object	Parameter	Value
ALWAYS_FALSE	interface Loopback999	line protocol	Down
ALWAYS_TRUE	interface Loopback0	line protocol	Up

Next, we will test the "route" object to test reachability to a specific prefix. I made two objects; one specific for the loopback /32 address, and one for a generic /24 for which we do not have an exact match. The former is up and the latter is down.

```
! XRv3
track XRV14_LOOPBACK_ROUTE
type route reachability
route ipv4 153.14.14.14/32
```

```
track XRV14_LOOPBACK_LESS_SPECIFIC
type route reachability
route ipv4 153.14.14.0/24
```

```
RP/0/0/CPU0:XRv3#show track XRV14_LOOPBACK_ROUTE
Track XRV14_LOOPBACK_ROUTE
  Ip route 153.14.14.14 255.255.255.255 reachability ip vrf default
  Reachability is UP
  First Hop interface GigabitEthernet0_0_0_0.534
  1 change, last change 15:53:12 UTC [snip]
```

```
RP/0/0/CPU0:XRv3#show track XRV14_LOOPBACK_LESS_SPECIFIC
Track XRV14_LOOPBACK_LESS_SPECIFIC
  Ip route 153.14.14.0 255.255.255.0 reachability ip vrf default
  Reachability is DOWN
  1 change, last change 15:54:13 UTC [snip]
```

Next, we will tie EOT to an IP SLA operation. EOT in XR does not support the “state” option, so measuring the threshold values inside EOT is not possible; only reachability appears is supported. The object below tracks the reachability of IP SLA ID 301 and when it times out, the object goes down. **This feature appears to be dysfunctional in XR v5.3.0 (it may be XRv-specific).** I have the IP SLA running successfully but EOT does not acknowledge it.

```
! XRv3
track XRV14_REACH
type rtr 301 reachability
```

```
RP/0/0/CPU0:XRv3#show ipsla statistics 301 | utility egrep 'Number|occurred'
  Number of operations attempted: 35
  Number of operations skipped   : 0
  Connection loss occurred       : FALSE
  Timeout occurred               : FALSE
```

```
RP/0/0/CPU0:XRv3#show track XRV14_REACH
Track XRV14_REACH
  Response Time Reporter 301 reachability
  ipsla operation not in progress
```

To test the object-list features, I will add three objects to track XRv3 loopback0 and its two transit interfaces to ensure the line-protocol is up. XR does not let me track the loopback using a route object, for some reason, but it the parser accepts it for the transit links.

```
! XRv3
track XRV3_TO_CSR1
type line-protocol state
interface GigabitEthernet0/0/0/0.513

track XRV3_TO_XRV4
```

```

type line-protocol state
interface GigabitEthernet0/0/0/0.534

track XRV3_LOOPBACK
type route reachability
route ipv4 153.13.13.13/32

```

The track process does not appear to actually track connected routes though, so using line-protocol is better for this test. I leave it in the configuration for Loopback0 as a demonstration.

```

! XRV3
track XRV3_LOOPBACK
type route reachability
route ipv4 153.13.13.13/32
!!% 'FIB' detected the 'warning' condition 'Invalid argument'

```

```

RP/0/0/CPU0:XRv3#show track brief | include XRV3
XRV3_LOOPBACK0      interface Loopback0                line protocol      Up
XRV3_TO_XRV4        interface GigabitEthernet0/0/0/0.534    reachability       Up
XRV3_TO_CSR1        interface GigabitEthernet0/0/0/0.513    reachability       Up

```

The logic of the weighted threshold list is very odd in XR. In XE, if the sum of the weights was higher than the up-value, the object was up. If the sum of the weights was lower than the down-value, the object was down. In XR, the sum of the weights must lie in the range of the two values to be up. The interesting thing about XR's implementation is that you can specify multiple threshold ranges, but the logical comparison between those ranges is Boolean AND. In this example, the list can suffer the loss of a single transit link only. The current sum of the weights is 20, which is within the range $11 \leq x \leq 20$.

```

! XRV3
track LIST_WEIGHT
type list threshold weight
object XRV3_TO_CSR1 weight 5
object XRV3_TO_XRV4 weight 5
object XRV3_LOOPBACK0 weight 10
threshold weight up 20 down 11

RP/0/0/CPU0:XRv3#show track LIST_WEIGHT
Track LIST_WEIGHT
List threshold weight is UP
4 changes, last change 16:18:24 UTC [snip]
object XRV3_LOOPBACK0 UP
object XRV3_TO_XRV4 UP
object XRV3_TO_CSR1 UP

```

Adding a bogus threshold brings the object down, because it's impossible that a number is $11 \leq x \leq 20$ and $400 \leq x \leq 500$ concurrently. This proves that Boolean AND logic is used between ranges.

```

! XRV3
track LIST_WEIGHT
  type list threshold weight
    object XRV3_TO_CSR1 weight 5
    object XRV3_TO_XRV4 weight 5
    object XRV3_LOOPBACK0 weight 10
    threshold weight up 20 down 11
    threshold weight up 500 down 400

RP/0/0/CPU0:XRv3#show track LIST_WEIGHT
Track LIST_WEIGHT
  List threshold weight is DOWN
  11 changes, last change 16:27:51 UTC [snip]
    object XRV3_LOOPBACK0 UP
    object XRV3_TO_XRV4 UP
    object XRV3_TO_CSR1 UP

```

Let's remove the bogus threshold (not shown). If we shut down the link to CSR1, the object stays up. This is because the sum of the weights becomes 15, which is valid ($11 \leq 15 \leq 20$).

```

RP/0/0/CPU0:XRv3#show track LIST_WEIGHT
Track LIST_WEIGHT
  List threshold weight is UP
  6 changes, last change 16:23:45 UTC [snip]
    object XRV3_LOOPBACK0 UP
    object XRV3_TO_XRV4 UP
    object XRV3_TO_CSR1 DOWN

```

If we also shut down the link to XRV4 while the link to CSR1 is still down, the object goes down since the weight becomes 10; this crosses the "down" threshold.

```

RP/0/0/CPU0:XRv3#show track LIST_WEIGHT
Track LIST_WEIGHT
  List threshold weight is DOWN
  7 changes, last change 16:25:24 UTC [snip]
    object XRV3_LOOPBACK0 UP
    object XRV3_TO_XRV4 DOWN
    object XRV3_TO_CSR1 DOWN

```

Even with both transit links up, shutting down the loopback brings the whole list down. The sum of the weights is 10, like the previous example, and the list is down for the same reason.

```

RP/0/0/CPU0:XRv3#show track LIST_WEIGHT
Track LIST_WEIGHT
  List threshold weight is DOWN
  9 changes, last change 16:25:51 UTC [snip]
    object XRV3_LOOPBACK0 DOWN
    object XRV3_TO_XRV4 UP

```

```
object XRV3_TO_CSR1 UP
```

The percentage threshold list is similar to the weighted one except all objects contribute equally to the list's status. A list with three objects allows each to contribute 33% to the list, and the threshold determines at what point is the list considered up. This list can tolerate the loss of up to one interface.

```
! XRV3
track LIST_PERCENT
type list threshold percentage
object XRV3_TO_CSR1
object XRV3_TO_XRV4
object XRV3_LOOPBACK0
threshold percentage up 100 down 66

! XRV3
Track LIST_PERCENT
List threshold percentage is UP
1 change, last change 16:33:06 UTC [snip]
object XRV3_LOOPBACK0 UP
object XRV3_TO_XRV4 UP
object XRV3_TO_CSR1 UP
```

First, we shutdown the loopback and notice the object stays up, unlike the weighted list.

```
RP/0/0/CPU0:XRv3#show track LIST_PERCENT
Track LIST_PERCENT
List threshold percentage is UP
3 changes, last change 16:35:10 UTC [snip]
object XRV3_LOOPBACK0 DOWN
object XRV3_TO_XRV4 UP
object XRV3_TO_CSR1 UP
```

Additionally, we shutdown the link to CSR1 and the object goes down as expected.

```
RP/0/0/CPU0:XRv3#show track LIST_PERCENT
Track LIST_PERCENT
List threshold percentage is DOWN
4 changes, last change 16:35:37 UTC [snip]
object XRV3_LOOPBACK0 DOWN
object XRV3_TO_XRV4 UP
object XRV3_TO_CSR1 DOWN
```

Access-list based forwarding (ABF) is the XR equivalent to policy-based routing (PBR) in XE. We use it here primarily to demonstrate object tracking by reusing some objects from earlier. The ACL prefers to route HTTP traffic to CSR1 if the interface is up, and prefers to route voice to XRV4 if that interface is up. Finally, it prefers to route telnet to CSR1 only if both interfaces are up. I created a Boolean AND list to accomplish this. I also used the ALWAYS_FALSE object and negated it to demonstrate the NOT feature

(the object is always true now). The output from the show command for tracked objects is interesting because it doesn't actually say ALWAYS_FALSE is "up", it just says "not" plus whatever the state is. I did not apply the list anywhere but left it in the configuration for reference.

```
! XRv1
track LIST_BOOLEAN_AND
type list boolean and
  object ALWAYS_FALSE not
  object XRV3_TO_CSR1
  object XRV3_TO_XRV4

RP/0/0/CPU0:XRv3#show track LIST_BOOLEAN_AND
Track LIST_BOOLEAN_AND
  List boolean and is UP
    1 change, last change 16:49:43 UTC [snip]
      object XRV3_TO_XRV4 UP
      object XRV3_TO_CSR1 UP
      object ALWAYS_FALSE not DOWN

! XRv3
ipv4 access-list ACL_POLICY_ROUTE
10 permit tcp any any eq www nexthop1 track XRV3_TO_CSR1 ipv4 153.1.13.1

30 permit tcp any any eq telnet nexthop1 track LIST_BOOLEAN_AND ipv4 153.1.13.1
```

48. Describe, implement, and troubleshoot MPLS OAM and Ethernet OAM

As a general comment, all MVPN OAM related commands are tested under their respective MVPN sections. There is too much variation between the MVPN profiles to integrate them intelligently below. The unicast OAM mechanisms are discussed in this section and used throughout many other labs.

48.1 MPLS ping, MPLS traceroute, and VCCV

MPLS ping and traceroute are valuable tools to capture more information about MPLS LSPs. They integrate well with IP SLA and are basic troubleshooting tools for MPLS network administrators. The network below uses basic L3VPN and L2VPN to test OAM functionality. CSR6, CSR7, and CSR8 are L3VPN customers while CSR9 and CSR10 are L2VPN customers. The routers in AS 1 make up the MPLS core.

The MPLS ping syntax is similar to an ordinary IPv4/v6 ping except instead of specifying a destination IP address, you specify a destination prefix, which represents a FEC. This is because MPLS label allocation mechanisms (LDP, BGP, etc) will bind labels to prefixes and the routing table might have multiple routes. For example, if CSR1 has an IGP route to 153.14.14.14/32 with an LDP label and another IGP route to 153.14.14.0/24 with a different LDP label, the MPLS ping allows us to test both FECs independently. Normally, pinging or tracerouting 153.14.14.14 by itself would always follow the /32 path unless it was not available (basic longest-match routing). The MPLS ping requires that the FEC being probed exists in the routing table with an appropriate label binding based on the supported FEC types (varies between platforms and versions). I've temporarily added 153.14.14.14/24 as a loopback on CSR5 and advertised it into IS-IS to demonstrate this (configuration not shown). The verbose option lets us see the source of the reply. We can clearly see different routers replying to each probe.

```
R2#ping mpls ipv4 153.14.14.14/32 source 153.2.2.2 verbose repeat 1
Sending 1, 72-byte MPLS Echos to 153.14.14.14/32,
    timeout is 2 seconds, send interval is 0 msec:
```

```
Codes: '!' - success, 'Q' - request not sent, '.' - timeout,
[snip]
```

```
Type escape sequence to abort.
```

```
!    size 72, reply addr 153.13.14.14, return code 3
```

```
Success rate is 100 percent (1/1), round-trip min/avg/max = 9/9/9 ms
Total Time Elapsed 9 ms
```

```
R2#ping mpls ipv4 153.14.14.0/24 source 153.2.2.2 verbose repeat 1
Sending 1, 72-byte MPLS Echos to 153.14.14.0/24,
    timeout is 2 seconds, send interval is 0 msec:
```

```
Codes: '!' - success, 'Q' - request not sent, '.' - timeout,
[snip]
```

```
Type escape sequence to abort.
```

```
!      size 72, reply addr 153.1.5.5, return code 3
```

```
Success rate is 100 percent (1/1), round-trip min/avg/max = 8/8/8 ms
Total Time Elapsed 8 ms
```

An interesting characteristic of the MPLS ping is that the destination of the IP packet inside of the MPLS ping is set to a local address (127.0.0.0/8). This ensures that if the LSP is broken, that packet will not simply be forwarded via IP routing. Using EPC on CSR1, we send the ping again via CSR2. The 4 bytes after the MPLS ethertype (0x8847) represent the top-most (and only) label in the stack currently. The value is 0x003E9 which is 1004 and highlighted in yellow; this is CSR1's label for 153.14.14.0/24. The S-bit is set and the TOS is zero since the next hex digit is 0x1 (0001). The TTL is 0xFF or 255 since the router has not decremented it yet. I also highlight the IP protocol, which is UDP (0x11 is 17 in decimal and highlighted green); we may have expected to see ICMP here. I highlight the source IP 0x99020202 which is CSR2's loopback in hex (cyan). Following that is the destination IP address 0x7f000001, which is 127.0.0.1, shown in pink. This is not a routable IP address. I also highlight the source and destination UDP ports 0x0DAF in grey, which is 3503, the well-known MPLS LDP ping port.

```
R1#show monitor capture CAP buffer detailed

```

```
R1#show mpls forwarding-table labels 1004
```

Local	Outgoing	Prefix	Bytes	Label	Outgoing	Next Hop
Label	Label	or Tunnel Id	Switched		interface	
1004	Pop Label	153.14.14.0/24	5884		Gi2.515	153.1.5.5

We know that due to PHP on CSR1, this is sent as raw IP to CSR5, which won't route the packet further. We theorize that the MPLS ping we just tested may not ensure that the link between the penultimate hop and the ultimate hop is MPLS enabled. To test this, we disable LDP on the link between CSR1 and CSR5. The LFIB used to "pop" the topmost label; now it removes all labels from the stack.

```
! CSR1
interface GigabitEthernet2.515
 no mpls ldp igp autoconfig
```

```
R1#show mpls forwarding-table 153.14.14.0 24
```

Local Label	Outgoing Label	Prefix or Tunnel Id	Bytes Switched	Label	Outgoing interface	Next Hop
1004	No Label	153.14.14.0/24	7024		Gi2.515	153.1.5.5

Fortunately, the LSP ping still tells us there is a fault as it reports “unlabeled interface”, but the ping still completes unsuccessfully. It does not timeout when you run it from exec, but IP SLA does report it as a timeout. This shows that we do have IP connectivity, but not MPLS connectivity.

```
R2#ping mpls ipv4 153.14.14.0/24 source 153.2.2.2
Sending 5, 72-byte MPLS Echos to 153.14.14.0/24,
 timeout is 2 seconds, send interval is 0 msec:
```

```
Codes: '!' - success, 'Q' - request not sent, '.' - timeout,
 'L' - labeled output interface, 'B' - unlabeled output interface,
```

Type escape sequence to abort.

```
BBBBB
```

```
Success rate is 0 percent (0/5)
```

```
Total Time Elapsed 11 ms
```

We can ensure the ping follows an LSP everywhere using “force-explicit-null”, which adds an explicit-null at the bottom of the stack. This way, there is no possible way a path could not be enabled for MPLS anywhere in the path. Now the manual test times out. This additional shim could also be valuable for testing MPLS fragmentation when coupled with large LSP pings.

```
R2#ping mpls ipv4 153.14.14.0/24 source 153.2.2.2 force-explicit-null
Sending 5, 72-byte MPLS Echos to 153.14.14.0/24,
 timeout is 2 seconds, send interval is 0 msec:
```

```
Codes: '!' - success, 'Q' - request not sent, '.' - timeout,
```

Type escape sequence to abort.

```
.....
```

```
Success rate is 0 percent (0/5)
```

```
Total Time Elapsed 9636 ms
```

We can introduce MPLS traceroute to troubleshoot this timeout problem. The command syntax is almost identical to the LSP ping, except we use the “traceroute” keyword. I’ve added TTL=2 so the failed traceroute dies quickly instead of trying to trace 30 hops. Notice that on hop index 1, there is no label stack at all. Traceroute indicates that the LSP suddenly ended along a FEC unexpectedly. The output

limits the scope of the problem to the link between CSR1 and CSR2, which is valuable for fault isolation and troubleshooting in large networks.

```
R2#traceroute mpls ipv4 153.14.14.0/24 source 153.2.2.2 force-explicit-null
ttl 2
```

```
Tracing MPLS Label Switched Path to 153.14.14.0/24, timeout is 2 seconds
```

```
Codes: '!' - success, 'Q' - request not sent, '.' - timeout,
       'P' - no rx intf label prot, 'p' - premature termination of LSP,
```

```
Type escape sequence to abort.
```

```
0 153.1.2.2 MRU 1500 [Labels: 1004/explicit-null Exp: 0/0]
```

```
p 1 153.1.2.1 9 ms
```

```
. 2 *
```

We will now shutdown this temporary /24 interface on CSR5 and use real FECs from now on. CSR1 enables LDP towards CSR5 again for cleanup (not shown). Another common return code is “Q” for source-quench. This means that the source didn’t even send the probe for some reason. On CSR1, I have filtered advertisement of the local label for 153.14.14.14/32 (temporarily).

```
! CSR1
ip access-list standard ACL_NO_XRV4_LABEL
deny 153.14.14.14
permit any
```

```
no mpls ldp advertise-labels
mpls ldp advertise-labels for ACL_NO_XRV4_LABEL
```

```
R1#show mpls ldp bindings 153.14.14.14 32 advertisement-acls
Advertisement spec:
Prefix acl = ACL_NO_XRV4_LABEL
```

```
R2#show mpls forwarding-table 153.14.14.14 32
```

Local	Outgoing	Prefix	Bytes Label	Outgoing	Next Hop
Label	Label	or Tunnel Id	Switched	interface	
2002	No Label	153.14.14.14/32	0	Gi2.512	153.1.2.1

Running the probe returns the “Q” flag as expected. Because the originating router doesn’t have a valid FEC there is nothing more to do. This is a way to see if the beginning of the LSP has MPLS/label issues.

```
R2#ping mpls ipv4 153.14.14.14/32 source 153.2.2.2
Sending 5, 72-byte MPLS Echos to 153.14.14.14/32,
timeout is 2 seconds, send interval is 0 msec:
```

```
Codes: '!' - success, 'Q' - request not sent, '.' - timeout,
```

```
Type escape sequence to abort.
```

00000

Success rate is 0 percent (0/5)

Total Time Elapsed 0 ms

The LSP ping tests LSPs; remember that LSPs are unidirectional. This means that the return path could be non-MPLS and the MPLS ping would still work. On CSR5, we create a new ACL to disallow CSR5 from advertising a label for CSR2's loopback. Return traffic cannot be MPLS encapsulated since XRv3 won't have a label for 153.2.2.2/32.

```
! CSR5
ip access-list standard ACL_NO_CSR2_LABEL
deny 153.2.2.2
permit any

no mpls ldp advertise-labels
mpls ldp advertise-labels for ACL_NO_CSR2_LABEL
```

RP/0/0/CPU0:XRv3#show mpls forwarding-table prefix 153.2.2.2/32

Local Label	Outgoing Label	Prefix or ID	Outgoing Interface	Next Hop	Bytes Switched
93003	Unlabelled	153.2.2.2/32	Gi0/0/0/0.535	153.5.13.5	0

The ping from CSR2 to XRv4 works but the opposite is not true. CSR2 has a valid LSP to 153.14.14.14/32 but XRv4 does not have a valid LSP to 153.2.2.2/32.

```
R2#ping mpls ipv4 153.14.14.14/32 source 153.2.2.2
Sending 5, 72-byte MPLS Echos to 153.14.14.14/32,
    timeout is 2 seconds, send interval is 0 msec:
[snip]

B size 100, reply addr 153.13.14.13, return code 9

Of note, XR routers must force exp-null if PHP occurs when using LSP ping. To test the LSP from XRv4 to CSR2, we use the following ping. I've set the EXP just to demonstrate the feature. The XE routers do not appear to be as strict when testing LSPs.

```
RP/0/0/CPU0:XRv4#ping mpls ipv4 153.2.2.2/32 source 153.14.14.14 force-  
explicit-null exp 4
```

```

```

Type escape sequence to abort.

```
!!!!
```

```
Success rate is 100 percent (5/5), round-trip min/avg/max = 1/6/20 ms
```

Both XE and XR can specify the FEC type for the LSP also by selecting LDP or BGP. Since we do not have BGP labeled-unicast configured, selecting that FEC-type results in a lack of FEC mapping for the LSP. I show both the XE and XR outputs. For XR, notice I include exp-null and the verbose option for variety.

```
R1#ping mpls ipv4 153.5.5.5/32 fec-type bgp source 153.1.1.1

```

The MPLS ping has some other interesting characteristics and options. All LSP probes use the IP option “router-alert” so that that IP packet is automatically punted to the CPU, bypassing any hardware dependencies on the probe target. This adds another 4 bytes of overhead to the IP header and cannot be disabled. The originator (head) of the probe can determine the “reply mode” for the receiver (tail). The default is an ordinary IPv4 UDP packet which may or may not be MPLS encapsulated; it depends entirely on how the tail end reaches the headend. The other option is to add the “router-alert” option to

the reply packet also to bypass hardware dependencies on the return path. This does not guarantee the LSP works in both directions, since they are unidirectional, but might be useful for troubleshooting. We will use some debugs to help us identify the presence or absence of the “router-alert” option. Using Wireshark, we can see what this option looks like because we have never seen it before. Once we see the bits, we can determine its hex string: 0x94040000. This will make it easily identifiable in EPC captures.

```

Options: (4 bytes), Router Alert
  Router Alert (4 bytes): Router shall examine packet (0)
    Type: 148
      1... .... = Copy on fragmentation: Yes
      .00. .... = Class: Control (0)
      ...1 0100 = Number: Router Alert (20)
    Length: 4
    Router Alert: Router shall examine packet (0)

```

Next, I will enable some MPLS LSP verification (lspv) debugging so we can see the key events and data packets. I will send a single LSP ping with reply-mode router-alert so I don't overwhelm the console. Notice the reply-mode is “3”; this is an identifier for the router-alert reply-mode. The outgoing packet shows the packet encapsulation for layer 3 and above (MPLS not included). I have highlighted the router-alert IP option in the request. Highlighted in green is the “number of 4-byte words” in the IP header, which is now 6. This implies that the IP header length is 24 bytes, not the standard 20. Notice that just before the router-alert option is the destination IP address, 127.0.0.1, which is shown in cyan. When the reply packet returns, the debug shows us the encapsulation for layer 2 and above. After sorting through the Ethernet and 802.1Q headers, we see the IP packet with the router-alert option set in the reply. Notice that the reply packet was 98 bytes in length.

```

Using the default reply-mode of IPv4, we see that the router-alert is still present in the request, but not in the reply. The response is 4 bytes shorter (94 versus 98) and we do not see the router-alert option in the IPv4 header of the echo-reply. This uses reply-mode “2” as the code; this is actually buried in the LSP payload and is not examined. I’ve highlighted the place the router-alert would have been, but in this case, it’s the first half of the UDP header which are the port numbers for LSP ping. Just for extra testing, I set reply DSCP EF to make sure the feature works (DSCP EF = 46 in decimal, 184 as TOS = 0xB8). I’ve also highlighted 0xB8 in green which is DSCP EF, present only on the reply, not the on request. The length of the reply IP header is 20 bytes again (5 words, no 6) since the router-alert option is absent. Lastly, I’ve highlighted the router-alert option in the request; it is always there.

We can also use the MPLS ping to probe routers for their downstream mappings (dsmap) for the FEC we are trying to reach. You must set the TTL accordingly to target specific routers in the path; in this case, I set TTL=1 from XRv4 so we can see what XRv3's label stack is. Not surprisingly, there is no label.

```
RP/0/0/CPU0:XRv4#ping mpls ipv4 153.2.2.2/32 source 153.14.14.14 dsmap ttl 1
repeat 1
Sending 1, 100-byte MPLS Echos to 153.2.2.2/32,
    timeout is 2 seconds, send interval is 0 msec:
```

```
Codes: '!' - success, 'Q' - request not sent, '.' - timeout,
       'L' - labeled output interface, 'B' - unlabeled output interface,
```

Type escape sequence to abort.

```
B Echo Reply received from 153.13.14.13
  DSMAP 0, DS Router Addr 153.5.13.5, DS Intf Addr 153.5.13.5
    Depth Limit 0, MRU 1500 [No Label]
[snip]
```

After removing the LDP label filter from CSR5, we repeat the command to see what XRv3's label binding should be. The query returns label value 5001. We could trace the entire LSP this way instead of using traceroute if we wanted to.

```
RP/0/0/CPU0:XRv4#ping mpls ipv4 153.2.2.2/32 source 153.14.14.14 dsmap ttl 1

```

One of the most powerful uses of the DSMAP is to determine load-sharing. Recall that MPLS performs load-sharing three possible ways: if the tunneled packet is IPv4 or IPv6, load-sharing is based on a hash of the source and destination addresses. If its non-IP traffic, load-sharing is based on the bottom label. We will specifically look at IPv4 here. But first, we need to change IGP to give us multiple paths. We change all of CSR5's transit links to metric 5 so CSR1 also has two equal-cost paths to XRv4 (not shown).

The total path cost will be 30 regardless of which path is selected. We verify load sharing on CSR1 via the LFIB show command.

```
R1#show mpls forwarding-table 153.14.14.14 32
```

Local Label	Outgoing Label	Prefix or Tunnel Id	Bytes Switched	Outgoing interface	Next Hop
1002	5004	153.14.14.14/32	146	Gi2.515	153.1.5.5
	93000	153.14.14.14/32	103394	Gi2.513	153.1.13.13

Next, we query CSR1 for its downstream label mappings from CSR2. Based on CSR1's LFIB above, we can see those labels are correct, but we see there are two "hash" buckets, 0 and 1 (highlighted), each corresponding to a different downstream path.

```
R2#ping mpls ipv4 153.14.14.14/32 source 153.2.2.2 ttl 1 dsmap repeat 1
Sending 1, 72-byte MPLS Echos to 153.14.14.14/32,

We can also ask the router what its multipath distribution looks like. Remember, ECMP with MPLS will be done based on the source/destination hash for IPv4 and IPv6 packets. Even though the destination is a 127.0.0.0/8 local-host address, this value does matter for load-sharing. MPLS ping takes advantage of this and the DSMAP can tell you, based on the destination (combined with a user-specified source), where the packet goes. We need to include a hashkey for IPv4 and, in a value called "bitmap", specify the number of addresses we want to see from that node for load-sharing. For example, given 8 different destination addresses, we reveal which addresses map to which paths. By doing this ahead of time, we can construct MPLS pings with the proper destinations to test all ECMP paths reliably and concurrently.

```
R2#ping mpls ipv4 153.14.14.14/32 source 153.2.2.2 ttl 1 dsmap hashkey ipv4

[snip]

We can send two MPLS pings from CSR2 to XRv4's loopback as the FEC target, but specify IPv4 destinations according to CSR1's DSMAP. We will clear CSR1's LFIB counters, then send a pair of pings. The first will not specify a destination since we know the default is 127.0.0.1, so this should use CSR5 for transport according to the DSMAP. Then, we will specify a destination of 127.0.0.6 to test the path via XRv3, because CSR2 said that address would be routed towards XRv3 in the DSMAP. We see almost exactly the same amount of bytes label switched (minor differences due to LDP/BGP session traffic, etc). Tying this destination address into IP SLA probes is an automated way to test all ECMP paths and is discussed later. This destination address is often referred to as the "LSP selector".

```

Aside from MPLS OAM, when we do a normal ping from CSR2 to XRv4 using the loopbacks, we can query CSR1 to see which way it would route the traffic by checking the LFIB. This command is similar to what we can do with CEF to determine which load-sharing paths are used. We need to specify the local (incoming) label, followed by the IPv4 or IPv6 source/destination pair. We see that CSR5 is the preferred transit path. I follow this verification with a quick ICMP ping test (assume counters have been cleared).

```
R1#show mpls forwarding-table exact-route label 1002 ipv4 source 153.2.2.2 destination 153.14.14.14
```

Local Label	Outgoing Label	Prefix or Tunnel Id	Bytes Label Switched	Outgoing interface	Next Hop

```
1002          5004          153.14.14.14/32  0          Gi2.515      153.1.5.5
```

```

```

```
R1#show mpls forwarding-table 153.14.14.14 32
```

Local Label	Outgoing Label	Prefix or Tunnel Id	Bytes Switched	Label	Outgoing interface	Next Hop
1002	5004	153.14.14.14/32	154768		Gi2.515	153.1.5.5
	93000	153.14.14.14/32	146		Gi2.513	153.1.13.13

Initially, this may sound suboptimal, because all of the MPLS traffic between this set of LSP endpoints will never use the link to XRv3. This is not true, since the VPN traffic plays a role also. For non-IP flows, the bottom-most VPN label influences the choice, and for IPv4/IPv6, the VPN source/destination influence it. Below is a coincidental and convenient example showing CSR6 sending traffic to CSR7 over MPLS. CSR1 it uses the link to XRv3 as shown below.

```
R1#show mpls forwarding-table exact-route label 1002 ipv4 source 6.6.6.6 destination 7.7.7.7
```

Local Label	Outgoing Label	Prefix or Tunnel Id	Bytes Switched	Label	Outgoing interface	Next Hop

```
R6#ping 7.7.7.7 source 6.6.6.6 repeat 100 size 1450
```

```
R1#show mpls forwarding-table 153.14.14.14 32
```

Local Label	Outgoing Label	Prefix or Tunnel Id	Bytes Switched	Label	Outgoing interface	Next Hop
1002	5004	153.14.14.14/32	350		Gi2.515	153.1.5.5
	93000	153.14.14.14/32	147746		Gi2.513	153.1.13.13

Verifying layer 2 circuits is a bit different. A pseudowire exists from CSR2 to CSR5 to test MPLS ping over that link. We will test its health using Virtual Circuit Connectivity Verification (VCCV). There are two key mechanisms of VCCV that are negotiated between the peers when tLDP is in use.

CV: Connectivity Verification. This is a 1-byte field in the VCCV parameter and describes the method by which the PW can be verified. There are two types:

ICMP Ping (0001 or 0x1): Uses ICMP for IPv4 or IPv6 depending on how the PW was established. Not supported by Cisco, at least on the CSR1000v and XRv.

LSP Ping (0010 or 0x2): Uses the usual UDP echo we saw earlier to test the PW. Inside the payload, it includes the FEC, reply-mode, and all the other details. This is what we have tested thus far.

CC: Control Channel. This is a 1-byte field in the VCCV parameter and determines the mechanics of performing the verification. There are three types:

Type 1: In-Band VCCV (0001 or 0x1): Using the PW associated channel header (PW-ACH), the signaling for VCCV is carried in the control-word (CW). This is the preferred VCCV mechanism and is what Cisco routers prefer. It is only used if CW capabilities are negotiated. The CW is discussed in great detail in the L2VPN section.

Type 2: Out-of-Band VCCV (0010 or 0x2): Uses the MPLS router-alert (RA) label as the second-to-bottom label, right above the PW label. When the topmost label is PHP'ed, the remote PE sees this router-alert and punts it to the CPU for processing. This is the next most preferable way to do VCCV if the control-word isn't present. The RA label has a value of 1 and can technically appear anywhere in the label stack except the bottom. Its purpose, in general, is identical to that of the router-alert IP option seen earlier.

Type 3: TTL Expiry VCCV (0100 or 0x4): Using TTL=1 on the PW label forces the packet to be examined by the remote PE's control-plane. This is the least preferable VCCV option but it does work as a last resort, and is what CSR1000v routers use when the PW-ACH option (type 1) is not available.

A router sets the appropriate bit to acknowledge supporting a given option during PW negotiation when tLDP is used for signaling. Looking at the VC bindings, we see that our CSR PEs support all three options. The debug output shows VCCV CC 0x7 (0111) which is the result of setting all three flags. We also see VCCV CV 0x2 (0010) which claims support for the LSP ping, or LSPV, but not ICMP ping. The output below shows what we advertised (local) and what we received (remote), including labels and VCCV capabilities. Based on this, our VCCV tests should be using PW-ACH control world signaling inside the LSP ping.

```
R2#debug mpls l2transport vc vccv event
R2#debug mpls l2transport signaling event
R2#debug mpls l2transport signaling message
```

```
AToM LDP[153.5.5.5]: Sending label mapping msg vc type 5, cbit 1,

```

We can also verify this with a show command. The legacy command is shown below; the newer alternative is “show l2vpn atom binding 90”. This book makes use for both methods for variety. In either case, the supported CC and CV capabilities are clearly shown so the administrator need not memorize the hexadecimal values.

```
R2#show mpls l2transport binding 90
Destination Address: 153.5.5.5, VC ID: 90
Local Label: 2011
  Cbit: 1,    VC Type: Ethernet,    GroupID: 0

  VCCV: CC Type: CW [1], RA [2], TTL [3]
  CV Type: LSPV [2]
Remote Label: 5008
  Cbit: 1,    VC Type: Ethernet,    GroupID: 0
  MTU: 1500,  Interface Desc: n/a
  VCCV: CC Type: CW [1], RA [2], TTL [3]
  CV Type: LSPV [2]
```

Next, we examine an LSP ping sent over a pseudowire. From CSR2, I initiate the probe while using EPC on CSR1, and I use EXP1 so we can more easily identify the traffic in the EPC buffer. The output from CSR1 contains many components: a two label stack, the PW-ACH, and the IP packet. The MPLS encapsulation is 8 bytes and is highlighted in yellow. The label stack is as follows: { 1001/EXP1/TTL255 }, { 5008/EXP1/S-bit/TTL1 }. Grey represents the PW-ACH information; the first nibble is always 0001 in binary while the last 2 bytes of 0x0021 represents IPv4 (IPv6 would be 0x0057). In green, we see the familiar IP source/destination addresses of 153.2.2.2 and 127.0.0.1, just like with the L3VPN verifications. In pink is the familiar 4-byte router-alert which is always present on the echo-request as an IP option. Last, in cyan, is the first half of the UDP header showing the well-known LSP ping port number 3503. It is important to understand that while the CW is an MPLS L2VPN component and is 4 bytes long, it is not an MPLS shim header and never carries a label value.

```
R2#ping mpls pseudowire 153.5.5.5 90 exp 1

R1#show monitor capture CAP buffer detail
16 134    1.076992  00:50:56:A9:BE:8A -> 00:50:56:A9:1A:AA MPLS unicast

```

For completeness, here is the response from CSR5. It’s nothing special, just a regular IP packet with a single MPLS label for transport (which technically doesn’t need to be there). The label 0x3E8 is 1000, which is what CSR1 advertised to CSR5 to reach 153.2.2.2/32. It appears that the default reply DSCP is CS6 (0xC0) in the IP header (green), which means EXP6 (0xC + 1 for S-bit = 0xD) in the shim header. Note that the default reply mode is IPv4, which means it not part of the PW LSP (no PW label, no CW, etc).

```

Let's instruct CSR2 not to use control word (CW) on its end of the PW. The PW flaps, and when it comes back up, we see different bindings, using both debug and show commands on CSR2.

```
! CSR2
interface pseudowire90
  control-word exclude
```

Even though we disabled CW on CSR2, this means that CSR5 is not willing to use that method to interact with CSR2. The debug shows CSR2 advertising support for the CW while CSR5 is not, which seems backwards. It's odd how both CSR2 and CSR5 both say CW is supported locally, but not remotely, even though only CSR2 withdrew the CW support.

```

```

We retest our LSP PW ping from CSR2 to CSR5, which succeeds. CSR2 uses CC type 3 (TTL expiry), as I do not see a router-alert label in the stack. It's the same packet as before except without the PW-ACH. The PW label has TTL=1 which forces CSR5 to examine it. Notice the PW label changed from 5008 to 5010 because when we removed CW support, the session flapped and a new label was allocated.

```
R2#ping mpls pseudowire 153.5.5.5 90 exp 1
```

```

```

Again, for completeness, here is the reply from CSR5, using label 1000 to reach CSR2's loopback. This is a regular IPv4 packet that happened to be MPLS encapsulated along the return path due to IGP/LDP, but is totally unrelated to the PW being tested (no PW label). Before continuing, we add the CW to this PW.

```

R1#show monitor capture CAP buffer detail

```

Label	Label	or Tunnel Id	Switched	interface	
5005	1000	153.2.2.2/32	16886	Gi2.515	153.1.5.1

Another useful debug command is shown below. For every LSP ping sent and received, a message is generated which clarifies the local and remote CW information. This is less destructive than flapping the PW and is a good addition to the show commands. The output below shows that all 3 VCCV CCs are supported; this makes sense since we added the CW back to this PW.

```
R2#debug l2vpn atom vc event
```

```
R2#ping mpls pseudowire 153.5.5.5 90 repeat 1
```

```
AToM[153.5.5.5, 90]: MSPW: LocCC CW [1], RA [2], TTL [3] Rem CW [1], RA [2], TTL [3]
AToM[153.5.5.5, 90]: MSPW: LocCC CW [1], RA [2], TTL [3] Rem CW [1], RA [2], TTL [3]
```

Pseudowire-based L2VPN does not appear to work in XRv at all, not even in the control plane.

```
! CSR5
interface pseudowire45
 encapsulation mpls
 neighbor 153.14.14.14 450
 vc type ethernet
 control-word exclude

! XRv4
l2vpn
 pw-class VPLS
 encapsulation mpls

xconnect group PW
 p2p CSR5
 interface GigabitEthernet0/0/0/0.998
 neighbor 153.5.5.5 pw-id 450
 pw-class VPLS
```

```
R5#show mpls l2transport vc 45 detail | include error
Last error: Remote peer access circuit is down
```

```
RP/0/0/CPU0:XRv4#show l2vpn xc pw-id 45 detail | include Error
Error: AToM Dynamic with mismatched AC config
```

However, static VPLS does appear to work in the control-plane on XRv, so we built a P2P VPLS connection from CSR5 to XRv4 to test XR VCCV. The PW never comes up because XRv always thinks there is a problem with its AC. I left the broken PW configuration there for reference in case it starts to work with newer code.

```

```
RP/0/0/CPU0:XRv4#show l2vpn bridge-domain pw-id 450 brief
```

Legend: pp = Partially Programmed.

Bridge Group:Bridge-Domain Name	ID	State	Num ACs/up	Num PWs/up
XR_VCCV:XR_VCCV	0	up	1/1	1/1

Next, we check XRv4 for its supporting VCCV capabilities. We can see the MPLS PW labels exchanged also. For completeness, we will examine CSR5's PW bindings also to see the MPLS label and VCCV information. We can see that the control-word VCCV capability was not negotiated; we will come back later and manually add the control word.

```

We inspect the EPC dump of these LSPV packets to determine whether they are using the router-alert label or not, since it's the only VCCV CC mechanism we have not observed. I will shutdown the link between XRv3 and CSR5 temporarily so CSR1 is always in the transit path. Again, I use EXP1 to help differentiate this traffic among everything else collected by CSR1. We see the CSR5 using the CC type-3 TTL-expiry method because the TTL on the PW label is 1 with no router-alert label or PW-ACH present.

```

We will test the LSP ping from XRv4 to see if it follows the RFC guidance and uses the router-alert over the TTL-expiry option. The output below proves that it does, in fact, use CC type-2 when the PW-ACH isn't available. The original label stack is shown in yellow while the router-alert label is shown in cyan. When the router obeys the RA label and looks at the underlying IP packet, it finds the familiar IP router-alert option and UDP destination port 3503, which indicates an LSPV message. Note that the TTL of the PW label is 255 which would never trigger type-3 VCCV.

```

I cannot find a way to allow XE to offer type-1 CC switching to XRv. I enable the control word successfully on both platforms as shown below.

```
! CSR5
interface pseudowire45
 control-word include

! XRv4
l2vpn
 pw-class VPLS
 encapsulation mpls
 control-word
```

The result is the same. The CW was successfully negotiated and could be used for non-VCCV functions such as sequencing. Both routers claim they have CW enabled, but only XR agrees to use PW-ACH for

VCCV. I assume this is a data-plane-related limitation of establishing a PW between the CSR1000v and XRv. We do not investigate it further.

```
RP/0/0/CPU0:XRv4#show l2vpn bridge-domain pw-id 450 detail | begin List of VFI

Control Word: On (configured: autosense)
```

Let's quickly retest in both directions to see what kind of VCCV CC mechanisms the routers use now that there is a disagreement about the best method. First, we will ping from CSR5 to XRv4. CSR5 used the PW-ACH control word (type-1 method) because XRv4 said it was capable of supporting it. The MPLS label stack is highlighted in yellow with the CW in cyan. In this way, it appears like the VCCV CC methods can be asymmetric; provided the CW is negotiated, CSR5 can use the PW-ACH for OAM but only in the transmitting direction.

```
R5#ping mpls pseudowire 153.14.14.14 450 exp 1
```

```

R1#show monitor capture CAP5 buffer detail

0030:  00019404 00000DAF 0DAF0050 8FC40001  .....P....

```

The next test involves testing the LSP in the reverse direction from XRv4 to CSR5. The ping totally fails. I theorize that XR is trying to play “by the rules” and send packets with a router-alert label, but CSR5 is not accepting it because it secretly doesn’t support it.

```

RP/0/0/CPU0:XRv4#ping mpls pseudowire 153.5.5.5 450 source 153.14.14.14 exp 1
[snip]
.....

```

XR has a great feature where you can actually pick which VCCV CC method you want to use. It’s tagged as “cisco-support” but I believe it’s useful for ordinary troubleshooting. By default, the router picks the “best” CC method available, which in this case is type-2 RA label method. If we quickly iterate over the other options, we see that type-1 CW does work, despite the CSR not advertising that capability in VCCV correctly. We also see that type-3 TTL-Expiry works as expected, but type-2 RA label does not. I am assuming the CSR simply does not support RA when it expects PW-ACH or TTL-Expiry to be used. We know the RA label worked before when CW was totally disabled and not negotiated on either end, assuming XRv4 initiates the LSP ping. It seems CSR5 did not clearly communicate its support for PW-ACH during the PW setup or else we wouldn’t have this problem.

```

force-control-channel ra-label
[snip]
.....

```

As a final test, we disable the CW from both sides to retest CC type-1 CW from XRv4 to see how CSR5 reacts. CW removal is not shown for brevity. A quick verification on CSR5 indicates CW is not a supported VCCV CC at either end. As expected, this fails, but both RA-label and TTL-expiry work.

Because this section continues into the next one using the same topology, the configurations are included only at the end of the next section.

48.2 MPLS LSP Monitor (MPLSLM) / LSP Health Monitor

Earlier we discussed IP SLA probes as tools to actively monitor network devices using specific ports, protocols, encapsulations, etc. Based on the last test with MPLS LSP load-sharing and testing each path, you can manually define some IP SLA probes to test the LSP health between PEs. Since IP SLA supports several MPLS probes, this is a good way to test LSPs to ensure traffic doesn't get blackholed or looped. The downside is that it is configuration intensive, prone to human error, and scales poorly. **MPLSLM is a feature used to automatically discover MPLS L3VPN PE devices and probe them via IP SLA.** This is tricky on XE because the manner in which things are configured (auto ip sla) is different than how they are verified (show ip sla auto). Older versions had more straightforward configuration syntax (ip sla auto).

The first step in configuring the "LSP Health Monitor", as it is sometimes called, is enabling MPLS L3VPN PE discovery. This is step simple; simply turn on the feature and tell the MPLS process how frequently to refresh its auto-discovered PEs using the BGP next-hop values. The default timer for scanning these new PEs is 300 (5 minutes) seconds, but we reduce it to 15 for faster discovery.

```

! CSR2
mpls discovery vpn interval 15
mpls discovery vpn next-hop

```

We can verify with some simple show commands. The command specifically shows the refresh interval and a list of BGP next-hops. Each next-hop specifies which VRF's are locally configured on that PE. In this case, only VRF OAM is in play. The router successfully discovered both CSR5 and XRv4 as remote PEs without adding any discovery traffic to the network or reconfiguring other MPLS LSRs.

```

R2#show mpls discovery vpn
Refresh interval set to 15 seconds.
Next refresh in 8 seconds

Next hop 153.5.5.5 (Prefix: 153.5.5.5/32)
      in use by: OAM

Next hop 153.14.14.14 (Prefix: 153.14.14.14/32)
      in use by: OAM

```

Having learned these remote VPN next-hops, the router can automatically spawn IP SLA probes to test LSP reachability to them. The probes can be LSP ping (echo) or traceroute (pathEcho) probes. I've configured an automatic probe [ID 10] which is effectively a template for all the BGP next-hops discovered thus far. The template has an ACL applied which specifies a list of PEs that we are allowed to probe. This might be useful to ensure you don't probe too many (or rogue) PEs in the network. A numbered, standard ACL must be used, and you must define the list before applying it.

```

! CSR2
access-list 45 permit 153.14.14.14
access-list 45 permit 153.5.5.5

auto ip sla mpls-lsp-monitor 10
  type echo ipsla-vrf-all
  access-list 45

```

If you apply the ACL before defining it, you are presented with the following error.

```

R2(config-auto-ip-sla-mpls-params)#access-list 45
%Access List 45 doesn't exist. There may be inconsistency in the filtering
due to this.

```

I've also defined the "secondary frequency" value. This is used only when a failure condition occurs (timeout or connection-loss) to more aggressively probe an LSP. When we schedule the probe later, we will use a frequency of 120 seconds. We specify secondary frequencies of 45 for connection-loss and timeout conditions, and this value should always be less (faster) than or equal to the schedule frequency. The default frequency and secondary frequency time values are 60 seconds. There are 3 options for configuring the secondary frequency and are listed below. There is no ability to set different secondary frequency values for connection-loss and timeout concurrently. We use the first method.

1. Specify secondary frequency for both timeout and connection-loss ("both") using a single value
2. Specify secondary frequency for timeout only
3. Specify secondary frequency for connection-loss only

```

! CSR2
auto ip sla mpls-lsp-monitor 10
  secondary-frequency both 45

```

When we manually originated MPLS pings, we specified the “destination” as a mechanism for load-sharing by selecting different local-host addresses (127.0.0.0/8). Within the context of IP SLA, this is the LSP-selector attribute. By specifying a value, we can determine which path our upstream LSRs take to reach the target FEC (the target is determined automatically). Earlier, we saw that using destinations 127.0.0.[2367] would send traffic through XRv3 directly rather than through CSR5, which was CSR2’s default choice. We will force traffic through XRv3 for this health monitor using LSP-selector 127.0.0.3.

```
! CSR2
auto ip sla mpls-lsp-monitor 10
  lsp-selector 127.0.0.3
```

Next, we will schedule the MPLSLM probe just like an ordinary IP SLA probe, except we prefix the command with “auto” as shown below. In the IP SLA discussion, we discussed group scheduling and its associated timers. Because this automatic template is essentially a group of probes, we must use group scheduling timers. The schedule-period is the timer by which probes are evenly started. With a schedule period of 30 seconds, one LSP probe will happen at t=0, and another at t=15, assuming there are 2 probes (implying 2 remote PEs). If I introduced a third PE and added it to ACL 45, the probes would start at t=0, t=10, and t=20. They are always spaced evenly when not using LSP path discovery (LPD) which is discussed later. We specified the path we wanted to take with the LSP-selector for this example. The probe process runs every 120 seconds (2 minutes).

```
! CSR2
auto ip sla mpls-lsp-monitor schedule 10 schedule-period 30 frequency 120
start-time pending
```

First, we will verify the configuration. We can check our “neighbors” which is effectively a list of PEs after being processed by the ACL. We also see the automatically assigned IP SLA probe IDs, along with the original template probe of 10. This command is different than the MPLS VPN discovery command since it shows that probes were actually spawned.

```
R2#show ip sla mpls-lsp-monitor neighbors
IP SLA MPLS LSP Monitor Database : 10
BGP Next hop 153.5.5.5 (Prefix: 153.5.5.5/32)
  ProbeID: 100007 (OAM)
BGP Next hop 153.14.14.14 (Prefix: 153.14.14.14/32)
  ProbeID: 100008 (OAM)
```

We notice that the probes are not working when we look at the basic IP SLA statistics for each probe. When we enable LSPV debugging on CSR2 as we did earlier when examining the router-alert, we notice an interesting IPv4 source address for the probe. The probe is using the transit link between CSR2 and CSR1 as its source address (153.1.2.2), shown in yellow. The destination LSP-selector is shown in green for completeness (127.0.0.3). There does not appear to be a way to set the source-address within the

auto IP SLA template for MPLSLM. I consider this a significant issue since OSPF and IS-IS prefix-suppression techniques for IPv4 are quite common in MPLS core networks.

```
R2#show ip sla statistics 100007 | include Number
Number of successes: 0
Number of failures: 8
```

```
R2#show ip sla statistics 100008 | include Number
Number of successes: 0
Number of failures: 8
```

```
R2#debug mpls lspv packet data
LSPV: Echo Request to be sent on IPv4 LSP, pathindex 0, size 100,
datagramsize 112
46 00 00 70 C0 89 40 00 01 11 09 E9 99 01 02 02
7F 00 00 03 94 04 00 00 0D AF 0D AF 00 58 C0 00
[snip]
```

For the purposes of testing this feature, I allow CSR2 to advertise its connected interfaces as IP prefixes inside its IS-IS link-state packet (not shown). XRv4 will have a route for 153.1.2.0/24 via XRv3 now. Restarting the auto IP SLA scheduler, we receive a new set of probe IDs and will check the statistics specifically for those. The reason one probe has 3 successes and the other has 2 is because of the schedule-period; they are spaced 15 seconds apart.

```
R2#show ip sla mpls-lsp-monitor neighbors
IP SLA MPLS LSP Monitor Database : 10
BGP Next hop 153.5.5.5 (Prefix: 153.5.5.5/32)
  ProbeID: 100009 (OAM)
BGP Next hop 153.14.14.14 (Prefix: 153.14.14.14/32)
  ProbeID: 100010 (OAM)
```

```
R2#show ip sla statistics 100009 | include Number
Number of successes: 3
Number of failures: 0
```

```
R2#show ip sla statistics 100010 | include Number
Number of successes: 2
Number of failures: 0
```

In Cisco's terms, this technique is considered "MPLSLM without LSP Discovery". The reason is because although we discovered the BGP next-hops, we manually selected the LSP inside the probe template using the LSP-selector option. In other words, we are not testing all possible ECMP paths and thus do not have a full picture of the MPLS forwarding health between CSR1 and XRv4. This new discovery process is detailed in Cisco's documentation. Below is a summary of the process:

1. We first discover the PEs via MPLS general discovery, which is a common step.

2. We build a discovery group per PE, which contains a list of LSPs to that PE. The number of paths will be 1, at worst, if there is no load-sharing along any path to that PE.
3. According to some algorithm, the process begins sending MPLS pings with varying destination addresses (127.0.0.1, 127.0.0.5, etc) to discover the ECMPs. Once the algorithm completes, the number of unique LSPs per PE will be known, along with their LSP-selectors. Assume that this number is N.
4. The IP SLA process will send N LSP pings with the recently computed LSP-selectors/outgoing interfaces as part of a single IP SLA superoperation. This means that the number of IP SLA instances grows proportionally with the number of PEs, not with the number of ECMPs. The single operation sends multiple probes and tracks them within the discovery group.

The LSP discovery process only works for L3VPN and only supports MPLS ping. MPLS traceroute and VCCV operations are not supported when using LSP discovery.

We will create a new auto IP SLA [ID 20] that can discover all the LSPs. Notice that we have no option to set the LSP-selector under this sub-configuration as it contravenes the purpose of LSP path discovery. Because the discovery group is an aggregated collection of sorts, we have some familiar IP SLA history options available, such as hours-of-statistics-kept. Since an MPLS network could be very large, we can constrain the “tree traces” (discovery process). The “scan-period” is an upper-bound on how long this process should take, measured in minutes. Tree traces are performed regularly when this interval expires. “Maximum-sessions” is a number that constrains how many tree trace requests (there is one per discovered LSP) can happen concurrently, and “session-timeout” specifies how long each request should take. You can also start the discovery process from any arbitrary local-host address using “lsp-selector-base”, with the default being 127.0.0.0. Of greatest significance is the scan-period which is set to 3 minutes, and we will see this in the debugs. “Timeout” and “interval” are not part of the discovery process and represent ordinary MPLS ping attributes already discussed.

```
! CSR2
auto ip sla mpls-lsp-monitor 20
  type echo ipsla-vrf-all
  path-discover
  maximum-sessions 4
  scan-period 3
  session-timeout 1
  interval 250

auto ip sla mpls-lsp-monitor schedule 20 schedule-period 30 frequency 120
start-time pending
```

When we schedule the probe, it is valuable to enable debugs to watch the discovery process. The first chunk of output is generalized information for this LSP monitor and is not specific to the LSP discovery process or LPD groups. It simply tells us that two PEs were discovered, probes were spawned, LPD groups were created around those probes (one group per PE), and tree traces were scheduled.

```
R2#debug ip sla trace mpls-lsp-monitor 20
```

```

```

The tree trace process begins for 153.5.5.5 (CSR5). We know there is only one path to CSR5 using label 1001 (I verify this by checking the LDP bindings also). We also see some of our limits set, such as maximum-sessions set to 4. After the algorithm finds the path (the output is unintelligible), the path is displayed along with the LSP-selector discovered by the path. The path is stored, the “found-paths” field is incremented, and the tree trace completes.

  lib entry: 153.5.5.5/32, rev 10
    remote binding: lsr: 153.1.1.1:0, label: 1001
```

Next, the tree-trace (TT) begins for XRv4. The initial output is similar to the TT for CSR5, except now that “Running TT” is set to 2; these two traces ran concurrently but I sorted the debugs by TT for readability. We can only have a maximum of 4 traces at once per the configuration; this is a way to throttle the TT process so it does not hog CPU/memory resources. The traces may take longer with these controls but it ensures the router doesn’t bog down. The algorithm runs twice to find both paths, since CSR1 can ECMP via CSR5 or XRv3 to reach XRv4. The downstream label from CSR2’s perspective is 1002 for both paths since CSR1 is the next-hop for both. I verify this as I did earlier using the LDP LIB. Since the next-hop uses the same label, the LSP-selector uses two different destination IPv4 addresses to force traffic down both paths. We see 127.0.0.0 and 127.0.0.2 used for paths 0 and 1, respectively.

```

IPSLA-AUTOMPLS_TRACE:OPER:20 Starting the rediscovery, timer expiry after
179931 (ms)
```

Many new show commands are available to view the status of this feature and its discovered LSPs. I will display them in sequence. The first command isn't terribly useful as it only reports the IP SLA superoperation ID. There is one per PE, not per LSP, and if the probe needs to test multiple LSPs, it sends multiple echo requests out under the umbrella of the IP SLA superoperation. Also, the ordinary IP SLA show commands no longer report a counter of success and failure, but only the most recent return code.

```
R2#show ip sla mpls-lsp-monitor collection-statistics
Entry number: 100011
Entry number: 100012
```

```
R2#show ip sla statistics 100011 | include return_code
Latest operation return code: OK
```

```
R2#show ip sla statistics 100012 | include return_code
Latest operation return code: OK
```

Examining the operational state of these probes is more valuable. Knowing that ID 100012 (to XRv4) has two paths and 100011 (to CSR5) only has one, we will examine the most interesting 100012 probe. The preamble is general information about the probe, along with the parent MPLSLM template number and statistical information. Of greater interest is the path list. We see two paths that appear identical at a glance; the only differentiator is the LSP-selector. The debugs indicated one path used a destination of 127.0.0.0 while the other used 127.0.0.2. The output is confusing and requires explanation. To see what the local-host destination is, convert the decimal number to hex, add in the dots, and convert it back as 4 separate bytes. For example 2130706434 is our second LSP and converts to 0x7F000002 in hex. Adding dots yields 7F.00.00.02, and converting to decimal per-byte yields 127.0.0.2. The value 2130706432 is 0x7F000000 in hex, which is 127.0.0.0 without the dots. Just displaying the local-host IPv4 address in the first place would have been much more convenient.

```
R2#show ip sla mpls-lsp-monitor lpd operational-state 100012
Entry number: 100012

```

Path Information :

Path Index	Outgoing Interface	Lsp Selector	Link Type	Conn Id	Adj Addr	NextHop Addr	Downstream Label Stack	Status
1	Gi2.512	2130706432	90	0	153.1.2.1	153.1.2.1	1002	OK
2	Gi2.512	2130706434	90	0	153.1.2.1	153.1.2.1	1002	OK

Earlier, we used the neighbors command when testing MPLSLM without LSP discovery. Here, we see some extra information, including the “OK” path count. This is a quick verification to see if LSP discovery worked. It also shows the probe IDs so you can dig deeper if needed. LPD is smart in that it differentiates between “OK” paths and broken paths.

```

R2#show ip sla mpls-lsp-monitor neighbors
IP SLA MPLS LSP Monitor Database : 20
BGP Next hop 153.5.5.5 (Prefix: 153.5.5.5/32) OK Paths: 1
  ProbeID: 100011 (OAM)
BGP Next hop 153.14.14.14 (Prefix: 153.14.14.14/32) OK Paths: 2
  ProbeID: 100012 (OAM)

```

Another good command for quick verification is shown below. It includes a well-defined legend at the top as well. It will show one row per LPD group, specify its ID, and specify its status. Individual path-level detail is not revealed here.

```

R2#show ip sla mpls-lsp-monitor summary
Index          - MPLS LSP Monitor probe index
Destination    - Target IP address of the BGP next hop
Status         - LPD group status
LPD Group ID   - Unique index to identify the LPD group
Last Operation Time - Last time an operation was attempted by
                  a particular probe in the LPD Group

```

Index	Destination	Status	LPD Group ID	Last Operation Time
20	153.5.5.5	up	100011	.15:03:30.002 UTC [snip]
20	153.14.14.14	up	100012	.15:03:15.001 UTC [snip]

Next, we simulate a failure on the link between CSR1 and CSR5. I will configure CSR5 not to advertise a label for 153.14.14.14/32, which means the path will be unlabeled from CSR1’s perspective. It is still an ECMP according to IGP, though. The LSP to 153.14.14.14/32 still has a path through XRv13, so the LPD group is considered “partially” up if at least one component LSP is operational. We expect no change to LPD group 100011 (CSR5) since we did not perform any filtering against the LDP binding for 153.5.5.5/32. Before applying the filter to CSR5, I first enable IP SLA debugs on CSR2 again so we can see the failures. After we apply the filter, let’s verify it worked by checking CSR1’s LFIB. The tree trace process only happens every 3 minutes, so we might have to wait a bit.

```
! CSR5
no mpls ldp advertise-labels
mpls ldp advertise-labels for ACL_NO_XRV4_LABEL
```

```
R1#show mpls forwarding-table 153.14.14.14 32
```

Local Label	Outgoing Label	Prefix or Tunnel Id	Bytes Switched	Outgoing interface	Next Hop
1002	93000	153.14.14.14/32	27140	Gi2.513	153.1.13.13
	No Label	153.14.14.14/32	0	Gi2.515	153.1.5.5

The debug information is below. First, we quickly acknowledge that the path to 153.5.5.5/32 is unchanged. There was only every 1 path to CSR5 and this is still functional.

```
! CSR2
IPSLA-AUTOMPLS_TRACE:OPER:20 LPD Rediscovery interval timer expired

IPSLA-AUTOMPLS_TRACE:OPER:20 Starting LPD Tree Trace for (153.5.5.5)
IPSLA-AUTOMPLS_TRACE:OPER:20 Running TT is 1 Limit is 4, Last BGP Hop is
153.5.5.5
IPSLA-AUTOMPLS_TRACE:OPER:20 LPD Group(100011): Starting Path Discovery
Session
IPSLA-AUTOMPLS_TRACE:OPER:20 LPD Group(100011): Target (153.5.5.5/32)
```

[snip]

```
IPSLA-AUTOMPLS_TRACE:OPER:20 Path 0 is OK
IPSLA-AUTOMPLS_TRACE:OPER:20 output-interface Gi2.512 source 153.1.2.2
destination 127.0.0.0
IPSLA-AUTOMPLS_TRACE:OPER:20 Path already exists, status is OK
```

Of greater interest is the path to XRv4 via CSR5. We can see that the TT algorithm detects the breakage and updates the MPLSLM process. The downstream label binding is still the same because CSR1 still allocates a label for 153.14.14.14/32. Just because a neighbor gives you a label binding for the target FEC does not mean the LSP is operational end-to-end. The first path via XRv3 is operational but the second path via CSR5 is not.

```
! CSR2

IPSLA-AUTOMPLS_TRACE:OPER:20 Paths (found/broken/unexplored) (1/1/0)
```

The following show commands can reveal the path breakage also. The first one is tricky because the path ID's returned in the debug output (0 and 1) do not correlate well with the indices here (1 and 2). Nonetheless, we can see an issue with one of the LSPs. The second command shows the status of the LPD group as "partial" because it still has at least one valid LSP to the destination in question. Last, the basic IP SLA show command still indicates the probe is OK overall. This is a dangerous condition because 50% of traffic could be blackholed as IGP still thinks using that path is acceptable. This is a good use-case for LDP/IGP synchronization, which was discussed in detail in the LDP section.

```
R2#show ip sla mpls-lsp-monitor lpd operational-state 100012 | begin Path_In
Path Information :
```

Path Index	Outgoing Interface	Lsp Selector	Link Type	Conn Id	Adj Addr	NextHop Addr	Downstream Label	Status
1	Gi2.512	2130706432	90	0	153.1.2.1	153.1.2.1	1002	Broken
2	Gi2.512	2130706434	90	0	153.1.2.1	153.1.2.1	1002	OK

```
R2#show ip sla mpls-lsp-monitor summary | begin Index.*Dest

```

```
R2#show ip sla statistics 100012 | include return_code
Latest operation return code: OK
```

Let's completely disable LDP on CSR1 on the link facing CSR5 (not shown). This will break the LSP for 153.5.5.5/32 since IGP does not have any ECMPs for it. In other words, the LPD group for 153.5.5.5 only ever had one path. After disabling LDP, let's ensure the LFIB shows an unlabeled path to 153.5.5.5/32. Before that, we enable debugs on CSR2 and look for the breakage.

```
R1#show mpls forwarding-table 153.5.5.5 32
Local Outgoing Prefix Bytes Label Outgoing Next Hop
Label Label or Tunnel Id Switched interface
```

```
1001      No Label      153.5.5.5/32      49254      Gi2.515      153.1.5.5
```

```
! CSR2
```

```
IPSLA-AUTOMPLS_TRACE:OPER:20 LPD Rediscovery interval timer expired
```

```
IPSLA-AUTOMPLS_TRACE:OPER:20 Starting LPD Tree Trace for (153.5.5.5)
```

```
IPSLA-AUTOMPLS_TRACE:OPER:20 Running TT is 1 Limit is 4, Last BGP Hop is
```

```
153.5.5.5
```

```
[snip]
```

```
IPSLA-AUTOMPLS_TRACE:OPER:20 Path 0 is Broken
```

```
IPSLA-AUTOMPLS_TRACE:OPER:20 output-interface Gi2.512 source 153.1.2.2
```

```
destination 127.0.0.0
```

```
IPSLA-AUTOMPLS_TRACE:OPER:20 Path already exists, status is Broken
```

```
IPSLA-AUTOMPLS_TRACE:OPER:20 [Labels: 1001 Exp: 0 ]
```

```
IPSLA-AUTOMPLS_TRACE:OPER:20 Process Status Event
```

```
IPSLA-AUTOMPLS_TRACE:OPER:20 Paths (found/broken/unexplored) (0/1/0)
```

Using the same three show commands, we see that the LPD group contains one broken path, the overall group is considered down (not partial), and the general IP SLA probe is failing. Before continuing, we remove all filters and enable LDP on all core interfaces to restore baseline network connectivity.

```
R2#show ip sla mpls-lsp-monitor lpd operational-state 100011 | begin Path_In
```

```
Path Information :
```

Path Index	Outgoing Interface	Lsp Selector	Link Type	Conn Id	Adj Addr	NextHop Addr	Downstream Label Stack	Status
1	Gi2.512	2130706432	90	0	153.1.2.1	153.1.2.1	1001	Broken

```
R2#show ip sla mpls-lsp-monitor summary | begin Index.*Dest
```

Index	Destination	Status	LPD Group ID	Last Operation Time
20	153.5.5.5	down	100011	.15:39:00.003 UTC [snip]
20	153.14.14.14	partial	100012	.15:38:45.001 UTC [snip]

```
R2#show ip sla statistics 100011 | include return_code
```

```
Latest operation return code: No connection
```

The feature is similar in XR. We will attempt to demonstrate it on XRv4 to discover CSR2 and CSR5. First, we need to enable PE discovery based on BGP next hops. This is part of the “ipsla” tree unlike in XE, which is more consistent with the configuration logic. The remaining configuration is very similar to XE. One key note is that we need to identify the LSP-selector on XRv4. To do this, we query CSR5 for its DSMAP so we can force traffic a given way. In this example, we will force it through CSR1 directly. We can use the IPv4 destination address of 127.0.0.1 or 127.0.0.2 to accomplish this. We will use the latter.

```
RP/0/0/CPU0:XRv4# ping mpls ipv4 153.2.2.2/32 dsmap hash-key ipv4 bitmap 4  
ttl 1 repeat 1
```

```
L Echo Reply received from 153.13.14.13
```

```
DSMAP 0, DS Router Addr 153.1.13.1, DS Intf Addr 153.1.13.1
```

```

    Depth Limit 0, MRU 1500 [Labels: 1000 Exp: 0]
    Multipath Addresses:
        127.0.0.1          127.0.0.2
    DSMAP 1, DS Router Addr 153.5.13.5, DS Intf Addr 153.5.13.5
    Depth Limit 0, MRU 1500 [Labels: 5005 Exp: 0]
    Multipath Addresses:
        127.0.0.3          127.0.0.4

```

I've added some other options like exp-null and EXP3 for variety. Otherwise, the configuration is as close to CSR2 as it can reasonably be.

```

! XRv4
ipsla
mpls lsp-monitor
monitor 310
type mpls lsp ping
exp 3
force explicit-null
lsp selector ipv4 127.0.0.2

schedule monitor 310
frequency 30
schedule period 10
start-time now

mpls discovery vpn
interval 60

```

XRv MPLSLM does not work at all. The discovery process never finds a remote PE, no matter what.
 Ordinary MPLS L3VPN is working perfectly, and clearly XRv4 has the VPN routes with PE loopbacks.

```

RP/0/0/CPU0:XRv4#show ipsla mpls discovery vpn
Next refresh after: 35 seconds
BGP next hop      Prefix          VRF          PfxCount
[no output]

```

```

RP/0/0/CPU0:XRv4#show bgp vpnv4 unicast vrf OAM
[snip]
Route Distinguisher: 1:14 (default for vrf OAM)
*>i6.6.6.6/32      153.2.2.2          0      100      0 678 i
*> 7.7.7.7/32      153.7.14.7         0      100      0 678 i
*>i8.8.8.8/32      153.5.5.5          0      100      0 678 i

```

All of the IP SLA debugs are marked as “cisco-support” on IOS XR. Enabling the seemingly relevant debug prints a message every time the discovery interval expires, but that’s all it does. The router provides no indication of a fault nor any discovered PEs.

```

RP/0/0/CPU0:XRv4#debug ipsla sub-agent mpls discovery

```

```
ipsla_sa[260]: DISC: Refresh interval expired
```

For completeness, I configure a second monitor [ID 320] to mirror the LSP discovery monitor configured on CSR2. As expected, it does not work either, since the PE discovery process is faulty. I even specify the VRF OAM for this second probe, in case the documentation was mistaken. The documentation states that not configuring an explicit VRF means all VRFs are monitored.

```
! XRv4
monitor 320
  type mpls lsp ping
  vrf OAM
  path discover
  session limit 4
  session timeout 1
  scan period 3

schedule monitor 320
  frequency 120
  schedule period 30
  start-time now
```

Additional Reading – Reference configurations "mpls-oam"

48.3 Ethernet Management Tools (CFM, OAM, and E-LMI)

The advent of carrier Ethernet (Ethernet as a WAN technology) has brought forth the need for many new protocols to manage these networks. Other WAN technologies, like frame-relay, ATM, and SONET/SDH all had built-in support for link-monitoring. Ethernet was designed as a LAN protocol, so these new tools are add-ons to the existing Ethernet technology to make it suitable for WAN use. Ethernet OAM in general is a sizable topic and some of the features are limited to switches for obvious reasons. The core technology labs use three Cisco ME-3400-24TS-A switches on version 12.2-60.EZ8.

48.3.1 Connectivity Fault Management (CFM) (802.3ag)

CFM is a service-level OAM tool used in carrier Ethernet networks for proactive connectivity monitoring, fault detection, and fault isolation. The general idea is that by defining certain Ethernet interfaces as endpoints, we can create different hierarchical domains for maintenance. The definition of these specific points enables ping/traceroute tools, as well as other alarm reporting which is commonly not available on Ethernet LANs. CFM introduces many new terms, which are defined below.

Maintenance End Point (MEP): These are administratively-defined interfaces within an Ethernet network which define maintenance boundaries. These can be thought of like IP addresses where pings/traceroutes can be sourced from, along with other CFM messaging. There are two flavors of MEPs.

- a. **Inward or “up”:** These are endpoints configured on a switch to bound the internal domain but are configured at the “other end” of the switch. For example, if a switch has port 1 connected to the internal domain and port 2 connected to an external domain, an “UP MEP” would be

configured on port 2, because that port faces inwards “towards the switch” inside the same domain. This uses the “relay function” to send CFM messaging into the domain; it would not make sense to send internal CFM messaging out of port 2, since that goes to an external node.

- b. **Outward or “down”:** These are MEPs configured on port 2, but actually send CFM messages out of that wire-side interface, rather than internally using the “relay function”. This might be used on a CE switch which terminates the highest level CFM domain (levels are discussed later). These can also be used inside a carrier’s network at the port level for hop-by-hop maintenance.

Maintenance Intermediate Point (MIP): These are administratively-defined or auto-configured on intermediate switches. They exist primarily to forward CFM messaging back and forth, and to respond to traceroute probes from MEPs. MIPs allow the Ethernet network to be segmented so that faults can be isolated quickly, though MIPs are not tied to service-instances.

MEP and MIPs treat CFM messages that arrive from the wire-side based on the level in which those packets exist:

- a. Lower levels: CFM drops these packets
- b. Same level: CFM processes these packets
- c. Higher level: CFM forwards these packets without processing them (transparent). This is also true from packets arriving from the relay function side (inside).

There are 8 possible levels (0-7) that can be configured with CFM. The lower levels imply smaller networks. An example of a common CFM design would include operators, service providers, and customers. The operators are providing transit service over certain geographical areas, but perhaps not end-to-end connectivity. They are responsible for their own OAM and device management. An SP may subcontract multiple adjacent operators to enable connectivity for a customer, and would be interested to see faults between (but not within) those operator networks, since the sum of those operator networks is the SP network. The customer is the highest layer which would want to see alarms from the PE-CE links; although unable to see intra-SP or intra-operator errors, having connectivity between CE devices means the circuit is functional. Alternatively, issues in the customer network or SP network need not be revealed to operators, and adjacent operators need not see errors from one another.

There are 5 types of CFM messages. All of them are described in detail later, but the summaries are below.

- 1. **Continuity check message (CCM):** This is primarily used by CFM to discover remote MEPs and is essentially a hello packet. They can also carry alarm information as required.
- 2. **Loopback message (LBM):** The equivalent of an ICMP echo.
- 3. **Loopback reply (LBR):** The equivalent of an ICMP echo-reply.
- 4. **Link trace message (LTM):** The equivalent of a traceroute probe.
- 5. **Link trace reply (LTR):** The equivalent of a traceroute reply (TTL expiry or port unreachable).

The initial configurations are done on three hardware ME-3400-24TS-A switches arrayed in a line. ME1 and ME2 are operator bridges and ME3 is an SP-owned bridge. The entire domain is owned by the SP, and due to a lack of hardware, the notional customers are not CFM-aware (dummy ports used).

The basic NNI, LACP, and trunking configurations are not shown. Ports 15 and 16 are bonded on ME1 and ME2 using LACP, which CFM supports. The first thing to do is getting the operator network set up. This will include basic CFM configuration, such as enabling the feature, creating domains, creating service instances, and identifying MIPs/MEPs to support each service instance. On both switches, we enable the feature globally (can also do it per-interface) using IEEE 802.1ag versus the pre-standard Cisco version. I also enable logging to assist with troubleshooting. We define a CFM domain at level 1, which is a low level, and then create a service instance for VLAN 10. It is in this VLAN that the CCMs will be sent; since CFM is service-oriented, this session is specific to VLAN 10, which might be a customer transit VLAN. We enable the CCM messaging on this interface which has a default interval of 10 seconds and a default hold-time of 3 times that (30 seconds). Since the LACP bond faces inward, that is the MIP, which operates at level 1 and services a handful of test VLANs. Port 9 connects to an external entity, like another operator or customer, but it is an inward-facing (up) MEP so it sends its messaging through the switch, out towards the LACP bond. This MEP is specific to the OPERATOR domain and OP1 service instance.

```
! ME1
ethernet cfm ieee
ethernet cfm global
ethernet cfm logging
ethernet cfm domain OPERATOR level 1
  service OP1 vlan 10
  continuity-check

interface Port-channel12
  ethernet cfm mip level 1 vlan 10-19

interface FastEthernet0/9
```

```
ethernet cfm mep domain OPERATOR mpid 101 service OP1
```

The configuration on ME2 is essentially identical, except it has two MEPs towards ME3. I used different MPIDs for these so they are treated separately for CFM. The LACP bond is still a MIP, and the MEPs are still inward-facing (up). Note that both MEPs are part of the same service instance (OP1).

```
! ME2
ethernet cfm ieee
ethernet cfm global
ethernet cfm logging
ethernet cfm domain OPERATOR level 1
    service OP1 vlan 10
    continuity-check

interface Port-channel12
    ethernet cfm mip level 1 vlan 10-19

interface FastEthernet0/13
    ethernet cfm mep domain OPERATOR mpid 102 service OP1

interface FastEthernet0/14
    ethernet cfm mep domain OPERATOR mpid 112 service OP1
```

Next, we can verify the basic configuration on each switch locally, starting with ME1. It has one domain named OPERATOR at level 1 with one service configured. The service supports VLAN 10 as well as the continuity check (CC) messages at 10 second intervals. The maintenance association (MA) is OP1, which was our custom name. The direction is UP; don't be fooled, this isn't like line-protocol or state, this is just the "direction" of the CFM MEP. This doesn't mean things are working yet.

```
ME1#show ethernet cfm domain OPERATOR
Domain Name: OPERATOR
Level: 1
Total Services: 1
  Services:
  Type Id   Dir CC CC-int Static-rmep Crosscheck MaxMEP Source MA-Name
  Vlan 10  Up   Y  10s      Disabled   Disabled   100    Static  OP1
```

Next, we will verify the MPs we configured. This will show both MEPs and MIPs, but you can filter it down with variations of the command. The MEP is associated with the OP1 service, is configured on port 9 statically, supports CCMs, uses VLAN 10, and has an internal MAC of 001d.4692.f700 (discussed later). Notice the level is "Up", but this does not mean the MEPs are communicating yet. The MIP is less involved as it is not tied to a service instance, but shows the port, internal MAC, and VLAN supported.

```
ME1#show ethernet cfm maintenance-points local domain OPERATOR
Local MEPs:

```

Total Local MIPs: 1

The brain MAC is used for UP MEPs to communicate with the internal CFM level via the bridge relay function. We can reveal it by looking at the CFM statistics command.

```

ME1#show ethernet cfm statistics | include BRAIN
BRAIN MAC: 001d.4692.f700

```

Next, we can check the remote MEPs from ME1's perspective. This is similar to checking IGP neighbors to see if the protocol actually converged. On ME1, we see two remote MEPs. One of them represents ME2 port 13 (MEP 102) and one represents ME3 port 14 (MEP 112). Notice that both of the interface states are "Up", but one of the port states is "blocking". This is due to STP; ME3 is the root for all VLANs, and port 13 is ME2's root port. CFM can still monitor this link even though production traffic won't use it; in this way, CFM can still monitor all links in the network regardless of their STP state. The MAC address for both entries is the same because like ME1, ME2's MEP is inward facing (UP) so it uses the bridge-relay function with the brain MAC address. In summary, this output shows that the MEPs have "discovered" one another, and is one of the most valuable CFM show commands.

```

ME1#show ethernet cfm maintenance-points remote domain OPERATOR

```

1	OPERATOR	Po12		
-	OP1	Vlan 10	N/A	
	N/A		3s	

MPID: 101 Domain: OPERATOR MA: OP1

We didn't configure the MEPs to find another statically, so we should explore the discovery mechanism. Starting with a basic packet debug on ME1, we can see the CCMs being sent to/received from ME2. ME1 only sends one CCM since it has only one MEP, yet ME2 sends two (one per MEP). They are spaced 10 seconds apart as expected. I use three different colors to show the different CCMs on the network. Since CCMs are critical to the maintenance of an Ethernet network, they are automatically marked with CoS 7.

```
ME1#debug ethernet cfm packets domain OPERATOR
Ethernet CFM level 1 domain OPERATOR service OP1 packet debugging is on

! ME1
08:24:17: CFM-PKT: Received a CC packet with MPID 102, level 1, vlan 10 from
interface Po12
08:24:21: CFM-PKT: Received a CC packet with MPID 112, level 1, vlan 10 from

vlan 10
08:24:28: CFM-PKT: Received a CC packet with MPID 102, level 1, vlan 10 from
interface Po12
08:24:31: CFM-PKT: Received a CC packet with MPID 112, level 1, vlan 10 from
interface Po12
08:24:37: CFM-PKT: Sending Up direction MEP 101 CC message, level 1, cos 7,
vlan 10
```

We will configure local SPAN on ME2 so we can see traffic entering and exiting the LACP bond. This will give us more insight as to the CFM CCM frame format.

```
! ME2
monitor session 1 source interface Po12
monitor session 1 destination interface Fa0/23 encapsulation replicate
```

Unlike Cisco's REP, Wireshark recognizes 802.1ag as a standard and gives us some additional information. We can see that the source MACs are the brain MACs we saw earlier, and the destination MAC is a multicast MAC of 0180.2c00.0031. Being multicast, this is flooded to all ports in the VLAN, and this is how MEPs discover one another. Later, we will see that the last digit of the MAC address corresponds to the CFM level; in this case, the operator is using level 1. The ethertype is 0x8902 so we know this is a non-IP protocol custom-built for CFM. Looking inside the PDU, we can see the domain name, service name, MPID, and other information revealed from the debug.

No.	Time	Source	Destination	Protocol	Length	Info

More debugging reveals what actually happens when these CCMs are received. The remote MEPs are “found”, and then the remote MEP (rmep) is added to the CC database (CCDB) with the appropriate information.

```
ME2#debug ethernet cfm events domain OPERATOR
Ethernet CFM level 1 domain OPERATOR service OP1 event debugging is on
```

```
! ME2
CFM-EVT: Found remote mep for domain OPERATOR, level 1 vlan 10, mpid 101 mac
001d.4692.f700
CFM-EVT: Updated rmep in MIP CCDB, domain OPERATOR level 1, vlan 10 mac
001d.4692.f700 intf Po12
```

Leaving this event-level debugging enabled, I will unplug both LACP member ports from ME2. The link should fail, and CFM should notify us in many ways. Since logging is enabled, we should see log messages as well as CCDB changes. The alarm indication signal (AIS) is raised since there is a defect condition on the LACP bond. This is a “down” failure since it is towards the remote MEP. The “U” failures on the next debug messages show that the local MEPs no longer have a MIP from which they can send CCMs.

```
! ME2
%E_CFM-6-ENTER_AIS_INT: Interface Port-channel12 enters AIS defect condition
for Down direction
CFM-EVT: CC error event 0x200 cause an errdb entry for level 1, vlan 10, mac
04c5.a453.d800, si 0x0, domain OPERATOR, csi OP1, mpid 8190, archive_time 100
lifetime 210000 idb 0x0 idb name NULL

CFM-AIS: AIS Defect condition for mep at Interface Fa0/14 vlan 10 level 1
period 60
```

```
%E_CFM-6-ENTER_AIS: local mep with mpid 112 level 1 VLAN 10 dir U Interface
Fa0/14 enters AIS defect condition
CFM-AIS: AIS Defect condition for mep at Interface Fa0/13 vlan 10 level 1
period 60
%E_CFM-6-ENTER_AIS: local mep with mpid 102 level 1 VLAN 10 dir U Interface
Fa0/13 enters AIS defect condition

CFM-SAA-EVT: MEP_DELETE for mpid=101 mac=001d.4692.f700 in domain OPERATOR
OP1 vlan 10
```

We can confirm the remote MEPs are no longer available by checking the CCDB on ME2.

```
ME2#show ethernet cfm maintenance-points remote domain OPERATOR
[no output]
```

In case we were not using syslog or debug to troubleshoot, the current CFM errors are also stored in memory. We see two errors at present. The first shows ME1's brain MAC and that its lifetime expired, meaning it is unreachable. It happened 122 seconds ago. The other indicates that the local switch received the AIS signal, which refreshes every 60 seconds by default as long as there is an error.

```
ME2#show ethernet cfm errors domain-id OPERATOR
-----
MPID Domain Id                      Mac Address      Type Id
   MA Name                          Reason           Lvl  Age
   Local MEP Info
-----
101  OPERATOR                      001d.4692.f700   Vlan 10
     OP1                          Lifetime Expired 1    122s
     MPID: 112 Domain: OPERATOR MA: OP1
-   OPERATOR                      04c5.a453.d800   Vlan 10
     OP1                          Receive AIS      1    29s
     MPID: 112 Domain: OPERATOR MA: OP1
```

The debug reveals the reason for the AIS signaling. Although it points to ports 13 and 14, the real issue is the LACP bond being down. Since these MEPs are useless without the relay function (and the MIP), the AIS alarm is against those MEPs.

```
! ME2
CFM-AIS: AIS Defect condition for mep at Interface Fa0/14 vlan 10 level 1
period 60
CFM-AIS: AIS Defect condition for mep at Interface Fa0/13 vlan 10 level 1
period 60
```

Restoring the link, we can see that CFM recovers fully. Several syslog messages are generated, along with debugs, to indicate that AIS conditions were cleared. The MEP discovery process happens again

```
! ME2
```

```
%E_CFM-6-EXIT_AIS_INT: Interface Port-channel12 exited AIS defect condition
for Down direction
CFM-EVT: Found remote mep for domain OPERATOR, level 1 vlan 10, mpid 101 mac
001d.4692.f700
[snip]
%E_CFM-6-EXIT_AIS: local mep with mpid 112 level 1 VLAN 10 dir U Interface
Fa0/14 exited AIS defect condition
%E_CFM-6-EXIT_AIS: local mep with mpid 102 level 1 VLAN 10 dir U Interface

```

Now that we have built an operator network, we will nest this inside of a larger service provider CFM domain at level 3. ME3 will be an auxiliary switch that the SP contributes to the CFM domain, and this will have MEPs on both ME1 and ME3. This implies that ME2's ports would all be MIPs for this SP domain. Since ME2 LACP bond to ME1 is already a MIP at level 1, this means any higher levels can automatically pass through it, so we don't need to do anything there. However, ports 13 and 14 will suddenly become MIPs for level 3 while remaining MEPs at level 1. This is supported, and makes sense; level 1 should not leak beyond the operator, but the operator is encompassed (nested) within the SP level 3 CFM domain. ME2 does not need any other configuration regarding services that the SP devices have on their MEPs. This greatly enhances CFM scalability because lower levels don't have to touch every single transit device when new CFM services are added by higher levels at the network edges.

```

! ME2
interface range FastEthernet0/13 - 14
 ethernet cfm mip level 3 vlan 10-19

```

Checking the local MIPs, we can see those two new ports as level 3 MIPs, which means traffic at level 3 or above can pass through. The LACP bond is still at level 1, which is fine, because 3 is greater than 1.

```

ME2#show ethernet cfm maintenance-points local mip
Local MIPs:
* = MIP Manually Configured

```

Level	Port	MacAddress	SrvcInst	Type	Id	Source
*3	Fa0/13	04c5.a453.d800	N/A	Vlan	10-19	
*3	Fa0/14	04c5.a453.d800	N/A	Vlan	10-19	
*1	Po12	04c5.a453.d800	N/A	Vlan	10-19	

Next, we will configure the services/MEPs on the endpoints. ME1 and ME3 have the same domain-level configurations, creating a new domain at level 3 and a single service instance to start. The only difference is the MPIDs they have. ME3 also needs to add ports 13 and 14 as MIPs at level 3, just like ME2 did, so that the bridge-relay functionality can be used to send CCMs from the MEPs towards ME2.

```

! ME1 and ME3
ethernet cfm domain PROVIDER level 3
 service SP vlan 10
 continuity-check

```

```

! ME1 only

```

We quickly debug CCMs to show the packets being exchanged every 10 seconds. Because the local SPAN session is still up on ME2, we can sniff the wire and see the CCMs there also. Notice the destination is now 0180.c200.0033, which has 3 as the last digit instead of 1. This shows the CFM level and is used for automatic and efficient filtering at the CFM boundaries since it can (probably) be hardware-offloaded.

```

We quickly check for errors and find none. We can assume that the multi-level CFM is functional.

```
ME3#show ethernet cfm errors domain-id PROVIDER service SP
[no output]
```

We can test these MEPs using ping and traceroute. First, we will test the intra-operator MEPs using the CFM loopback messages, which are basically Ethernet pings. The syntax is straightforward where we specify the remote MPID, domain, and service instance. Based on this, the switch looks in the CCDB for a matching remote MEP. This determines the destination MAC address (remote brain MAC) along with the contents of the message so that the proper MEP is probed. From ME1, we will probe ME2's port 13 MEP.

```
ME1#ping ethernet mpid 102 domain OPERATOR service OP1
```

Type escape sequence to abort.

Sending 5 Ethernet CFM loopback messages to 04c5.a453.d800, timeout is 5 seconds:!!!!

Success rate is 100 percent (5/5), round-trip min/avg/max = 1/3/8 ms

Wireshark identifies these packets as loopback messages (LBM) and loopback replies (LBR), which are probes and responses, respectively. There isn't much detail in the packet other than identifying the type (LBM vs. LBR) with the source/destination MAC addresses, along with the CFM level. Notice the unicast destination of the LBM and LBR messages.

 CFM TLVs

We can also ping across the provider domain to the MEP on ME3. This is allowed because CFM messages of a higher level can transparently pass through MEPs/MIPs at lower levels.

```
ME1#ping ethernet mpid 203 domain PROVIDER service SP
```

Type escape sequence to abort.

Sending 5 Ethernet CFM loopback messages to 001f.9d0b.1680, timeout is 5 seconds:!!!!

Success rate is 100 percent (5/5), round-trip min/avg/max = 1/4/9 ms

Traceroute is very powerful as well. Before actually testing it, we can enable the traceroute cache on all switches. Unlike IPv4/v6 traceroutes, CFM traceroutes can be stored in memory for a certain amount of time and up to a certain quantity. These records can assist with troubleshooting over time. I slightly adjust the default size of 100 entries and default time of 100 minutes for demonstration. We can clear the cache (thought it is currently empty) using the command below.

```
! All ME switches
ethernet cfm traceroute cache
ethernet cfm traceroute cache size 512
ethernet cfm traceroute cache hold-time 120
```

```
ME1#clear ethernet cfm traceroute-cache
```

Now, we will perform some traceroutes. First, we will traceroute from ME1 to ME2 inside of the operator level. This is pretty boring since there is only one hop between MEPs, but we learn valuable link information. The MEP on ME1 (source) counts as an intermediate bridge as well, which is why there are “2 hops”. We can clearly see the ingress and egress interfaces, forwarding actions, brain MACs, and relay activity. Compared to IPv4/v6 traceroutes, CFM provides much greater detail.

```
ME1#traceroute ethernet mpid 102 domain OPERATOR service OP1
Type escape sequence to abort. TTL 64. Linktrace Timeout is 5 seconds
Tracing the route to 04c5.a453.d800 on Domain OPERATOR, Level 1, service OP1, vlan 10
Traceroute sent via Po12, path found via FDB
```

		Not Forwarded			001d.4692.f700

Looking at Wireshark, we can see a new pair of messages, link trace message (LTM) and link trace reply (LTR). The LTR shows some new interesting fields, such as a TTL value, original/target addresses, and a transaction ID. The multicast destination MAC addresses changes based on the level plus 8. For example, at level 1, the CCMs used a last digit of 1, and the LTRs use a last digit of 9. This helps support my argument that the internal CFM filters are hardware-assisted because, in binary, 1 and 9 are identical with the exception of the first bit in the nibble (0001 versus 1001). The CFM domain can ignore the first bit and only look at the last 3 for filtering. An LTR at level 7, for example, would use a value of F, while the CCMs would use 7 (1111 vs. 0111). The original/target unicast MAC addresses are contained within the payload of the LTM frame as seen below.

No.	Time	Source	Destination	Protocol	Length	Info
	7.093757000	00:1d:46:92:f7:00	01:80:c2:00:00:39	CFM	60	Type Linktrace Message (LTM)
	7.101550000	04:c5:a4:53:d8:00	00:1d:46:92:f7:00	CFM	78	Type Linktrace Reply (LTR)
<

+ TLV: End TLV (t=0,l=0)						

The LTR is much more interesting since it contains all of the important information shown in the traceroute reply. The ingress and egress details are carried in their own TLVs along with the relevant ingress/egress brain MACs.

A more interesting example involves tracing across the provider CFM domain from ME1 to ME3. Here, we can see both ME1 and ME2 are intermediary bridges, with ME3 as the final termination point. Notice that the details of the operator network (LACP bond, etc) are not included in this traceroute. Only the MIPs/MEPs relevant for level 3 are shown. This gives the operators some level of “privacy” since the larger levels only care about having service and testing the “seams”. The LACP bond does not support processing any CFM traffic above level 1, which is why the LTM is transparently passed through. No egress record is added by ME1 and no ingress record is added by ME2, which hides the operator domain from the provider. Instead, the level-3 MIP on ME2’s port 13 responds with a successful egress action as expected. The brain MACs of all switches that have level-3 MPs are revealed in the proper sequence.

```
ME1#traceroute ethernet mpid 203 domain PROVIDER service SP
Type escape sequence to abort. TTL 64. Linktrace Timeout is 5 seconds
Tracing the route to 001f.9d0b.1680 on Domain PROVIDER, Level 3, service SP, vlan 10
Traceroute sent via Po12, path found via FDB
```

B = Intermediary Bridge
 ! = Target Destination
 * = Per hop Timeout

Hops	Host	MAC Forwarded	Ingress Egress	Ingr Action Egr Action	Relay Action Previous Hop

! 3		001f.9d0b.1680	Fa0/13	IngOk	RlyHit:MEP

The LTR is shown below. There is only one LTM that is sent, unlike IP traceroute where subsequent TTL expirations cause more probes to be sent. The probe is relayed by the forwarding database (RlyFDB) which means it was successfully passed along. The reason the first LTR is only 62 bytes is because it didn't contain an ingress record TLV, as shown above. The final LTR is shown below where both the ingress and egress statuses are displayed from the remote MEP's response. The middle LTR was generated by the level-3 MIP, which is why MIPs are important to the CFM architecture.

```

After performing valuable diagnostic tests like ping and traceroute, we can check the statistics of them. The LTR (traceroute reply) statistics are limited to unexpected LTR receptions, which should always be 0. The LBRs (ping reply) are counted even when they pass, and given two sets of pings (I only showed one for the PROVIDER domain), a total of 10 good LBRs were received. This also counts CCMs transmitted, which is good way to tell if the MEP is even sending CCMs at all. I also show ME3's statistics for the PROVIDER domain because it shows 10 LBR's transmitted, since it was the device hosting the MEP replying to the pings.

```

ME1#show ethernet cfm statistics domain PROVIDER service SP

```

To support multiple customers, a single domain can have multiple services. On ME1 and ME3, we will create another service called SP_STATIC using VLAN 11. We will apply several minor options to this service. First, we statically identify the remote MEPs we expect to see within the domain, which can be used for additional strictness on neighbor formation. We enable CCMs for this new service and we tune their interval to be much faster at 1 per second. We permit the loss of up to 5 CCMs versus the default of 3, so MEP failure detection should be about 5 seconds. We can apply the MEPs to the same port as the other MEPs provided we have a different MPID and service tag. Under the service details, I adjust the CoS of the packets to 4 (default is 7 as seen earlier) and enable all possible alarms.

```
! ME3
ethernet cfm domain PROVIDER level 3
  service SP_STATIC vlan 11
    mep mpid 213
    continuity-check
    continuity-check interval 1s
    continuity-check loss-threshold 5
    continuity-check static rmep

interface FastEthernet0/9
  ethernet cfm mep domain PROVIDER mpid 213 service SP_STATIC
  cos 4
  alarm notification all

! ME1
ethernet cfm domain PROVIDER level 3
  service SP_STATIC vlan 11
    mep mpid 213
    continuity-check
    continuity-check interval 1s
    continuity-check loss-threshold 5
    continuity-check static rmep

interface FastEthernet0/9
  ethernet cfm mep domain PROVIDER mpid 211 service SP_STATIC
  cos 4
  alarm notification all
```

We will perform our verifications from the perspective of ME1. Using a long show command, we will print out the details of the specific MEP we just added. Although there are no defects at present, I highlight this field because it is useful for checking defects associated with MEPs when problems do arise. The most significant information is at the top, and we confirm that it is correct.

```
ME1#show ethernet cfm maintenance-points local detail mep domain PROVIDER
service SP_STATIC
Local MEPs:
-----
MPID: 211
```

```
DomainName: PROVIDER
MA Name: SP_STATIC
Level: 3
Direction: Up
Vlan: 11
Interface: Fa0/9
CC Offload: No
CC-Status: Enabled
CC Loss Threshold: 5
MAC: 001d.4692.f700
LCK-Status: Enabled
LCK Period: 60000(ms)
LCK Expiry Threshold: 3.5
Level to transmit LCK: Default
Defect Condition: No Defect
presentRDI: FALSE
AIS-Status: Enabled
AIS Period: 60000(ms)
AIS Expiry Threshold: 3.5
Level to transmit AIS: Default
Suppress Alarm configuration: Enabled
Suppressing Alarms: No
Source: Static
```

We can likewise verify the remote MPID using a detailed show command. We see that the interface/port states are up for this peer and that the remote defect indication (RDI) is not set. No CCMs have been received in error, either.

```
ME1#show ethernet cfm maintenance-points remote detail mpid 213
Version: IEEE-CFM
MAC Address: 001f.9d0b.1680
Domain Name: PROVIDER
MA Name: SP_STATIC
Level: 3
VLAN: 11
MPID: 213
Incoming Port(s): Port-channel12
CC Lifetime(sec): 5.500
Age of Last CC Message(sec): 0
CC Packet Statistics: 1416/0 (Received/Error)
MEP interface status: Up
MEP port status: Up
Receive RDI: FALSE
```

Debugging packets on ME1 reveals the CCMs for this new service. They arrive very quickly, one per second, and are sent at the same rate. We verify the MPID, VLAN, and CoS as well of the packets we originate.

```
ME1#debug ethernet cfm packets domain PROVIDER service SP_STATIC
Ethernet CFM level 3 domain PROVIDER service SP_STATIC packet debugging is on
```

```
00:23:04: CFM-PKT: Received a CC packet with MPID 213, level 3, vlan 11 from

```

```
00:23:05: CFM-PKT: Received a CC packet with MPID 213, level 3, vlan 11 from
interface Po12
```

```
00:23:05: CFM-PKT: Sending Up direction MEP 211 CC message, level 3, cos 4,
vlan 11
```

We can verify connectivity using the ping utility again to generate LBMs. Rather than perform another unicast Ethernet ping, we can perform a multicast Ethernet ping. This is a handy way to discovery other MEPs on the segment using the same destination MAC address used for CCMs at the domain's CFM level. Since we are pinging within CFM level 3, the destination MAC should be 0180.c200.0033. We see one response from 001f.9d0b.1680, which is the brain MAC of ME3.

```
ME1#ping ethernet multicast domain PROVIDER service SP_STATIC
Type escape sequence to abort.
Sending 5 Ethernet CFM loopback messages to 0180.c200.0033, timeout is 5
seconds:
Reply to Multicast request via interface Port-channel12, from 001f.9d0b.1680,
0 ms
Total Loopback Responses received: 1
```

For variety, I follow up with a unicast ping to this destination after having just discovered it. We can also specify the brain MAC as the destination, along with minor options like size and CoS adjustments.

```
ME1#ping ethernet 001f.9d0b.1680 domain PROVIDER service SP_STATIC cos 3 size
555
Type escape sequence to abort.
Sending 5 Ethernet CFM loopback messages to 001f.9d0b.1680, timeout is 5
seconds:!!!!
Success rate is 100 percent (5/5), round-trip min/avg/max = 1/1/1 ms
```

Next, we will examine CFM errors in greater detail. This is a very powerful feature of CFM since it tells you exactly what the problem is, and where. There are 5 main error codes which are described clearly in "IEEE8021-CFM-MIB-200811180000Z.txt":

Defect	Priority	Description
DefXconCCM	1 (highest)	Received CCM from another maintenance domain or a lower CFM level. These are fundamental CFM violations; cross-connect error.
DefErrorCCM	2	Received invalid CCM; often due to unknown MEP or loop error.
DefRemoteCCM	3	Not receiving valid CCMs from a valid RMEP; missing MEP.
DefMACStatus	4	Failure in the port-status TLV; MEP is down.

DefRDICCM	5 (lowest)	Received a valid CCM from the peer, but RDI is set to indicate a remote fault; check peer for error condition.

Just like with syslog, we can adjust what the is least important event that is still important enough to generate error conditions. In the previous example, we enabled all alarm notifications, which is loosely analogous to syslog level 7 (debug). Rather than describe each one, below is the context-sensitive help. I've rearranged the output to sort them in order from least restrictive (all) to most restrictive (none) which makes it easier to read. By default, RDI CCM events are not reported, which I've highlighted.

```
ME1(config)#ethernet cfm alarm notification ?
  all                      Report all defects: DefRDI, DefMACStatus, DefRemote,
                          DefError, DefXcon
  mac-remote-error-xcon    Report only: DefMACStatus, DefRemote, DefError and
                          DefXcon (default)
  remote-error-xcon        Report only: DefRemote, DefError and DefXcon
  error-xcon               Report only: DefError and DefXcon
  xcon                     Report only: DefXcon
  none                     No defects to be reported
```

Next, we will examine the particular errors in more detail. Since the CCMs are being verified against a static configuration with the SP_STATIC service instance, we can change one of the RMEP lists on either switch to break it. On ME1, I remove RMEP 213 and replace it with an invalid RMEP 99. This means ME1 is going to review CCMs from MPID 213 despite it not being configured. It will also fail to receive CCMs from MPID 99 which is configured. Both of these are faults.

```
! ME1
ethernet cfm domain PROVIDER level 3
  service SP_STATIC vlan 11
  no mep mpid 213
  mep mpid 99
```

Immediately upon entering this configuration, ME1 generates a log message indicating a fault alert. Based on the table above, we know that this is due to an invalid RMEP.

```
! ME1
%E_CFM-3-FAULT_ALARM: A fault has occurred in the network for the local MEP
having mpid 211 vlan 11 for service MA name SP_STATIC with the event code
DefErrorCCM.
```

We have two different errors as described above. First, we see CCMs from RMEP 213 which is not configured, and is thus considered invalid. Second, we have RMEP 99 configured but don't see it anywhere in the CCDB, so there is no brain MAC for it. The switch doesn't know what the "right" answer is, but this is a likely indication of a misconfiguration.

```
ME1#show ethernet cfm errors domain-id PROVIDER service SP_STATIC
```

MPID	Domain Id	Mac Address	Type	Id
	MA Name	Reason	Lvl	Age
	Local MEP Info			
99	PROVIDER	0000.0000.0000	Vlan 11	
	SP_STATIC	RMEP missing	3	0s
	MPID: 211 Domain: PROVIDER MA: SP_STATIC			
213	PROVIDER	001f.9d0b.1680	Vlan 11	
	SP_STATIC	Unknown MEP	3	0s
	MPID: 211 Domain: PROVIDER MA: SP_STATIC			

Shortly thereafter (as soon as ME1 sends the message), ME3 is aware of some issue. From ME3's perspective, there is no problem with the network, since the RMEP it has configured is still correct. The error message indicates that a CCM was received from MPID 213 with RDI set within the CCM. This indicates some fault with the RMEP; it is ME1's way of saying "I have a problem and need help". When we look at the error table, we don't get much detail other than having received a CCM with RDI set. The value of this cursory check is that it tells us the MPID and brain MAC of the defective device. From ME3's perspective, this doesn't help with fault identification, but it does help with fault isolation.

! ME3

```
%E_CFM-3-FAULT_ALARM: A fault has occurred in the network for the local MEP
having mpid 213 vlan 11 for service MA name SP_STATIC with the event code
DefRDICCM.
```

```
ME3#show ethernet cfm errors domain-id PROVIDER service SP_STATIC
```

MPID	Domain Id	Mac Address	Type	Id
	MA Name	Reason	Lvl	Age
	Local MEP Info			
211	PROVIDER	001d.4692.f700	Vlan 11	
	SP_STATIC	Receive RDI	3	0s
	MPID: 213 Domain: PROVIDER MA: SP_STATIC			

Unlike ME1, ME3 actually has MPID 211 in its database but sees RDI is enabled. There isn't an error with the CCMs per se, but this is ME1's way of signaling an issue as stated earlier.

```
ME3#show ethernet cfm maintenance-points remote detail mpid 211
```

```
Version: IEEE-CFM
MAC Address: 001d.4692.f700
Domain Name: PROVIDER
MA Name: SP_STATIC
Level: 3
VLAN: 11
MPID: 211
Incoming Port(s): FastEthernet0/13
CC Lifetime(sec): 5.500
Age of Last CC Message(sec): 0
```

```
CC Packet Statistics: 2654/0 (Received/Error)
MEP interface status: Up
MEP port status: Up
Receive RDI: TRUE
```

Checking ME1's local MEP detailed status, we can see that AIS is identified as the defect condition and RDI is presented to any remote peers of this MPID.

```
ME1#show ethernet cfm maintenance-points local detail mep domain PROVIDER
service SP_STATIC | begin AIS
Defect Condition: AIS
presentRDI: TRUE
AIS-Status: Enabled
AIS Period: 60000(ms)
AIS Expiry Threshold: 3.5
Level to transmit AIS: Default
Suppress Alarm configuration: Enabled
Suppressing Alarms: No
Source: Static
```

To continue detailed verification, we enable debugs on ME1. Because an invalid CCM has been received from MPID 211 (the unspecified RMEP), the CCMs are discarded. The error codes are included in the debugs also. The same debugging on ME3 reveals similar output and shows the reception of RDI CCMs. The defects are ignored because those are already the "highest" defects in the error tables. On ME1, we see a DefRemoteCCM which relates to MPID 99 being configured but receiving no CCMs. DefErrorCCM relates to the RMEP 213 CCMs being received but invalid due to not having MPID 213 configured. The DefErrorCCM issue is a "bigger deal" as it is a higher priority fault.

```
ME1#debug ethernet cfm events domain PROVIDER service SP_STATIC
Ethernet CFM level 3 domain PROVIDER service SP_STATIC event debugging is on

! ME1
00:52:28: CFM-EVT: Ignoring defect DefRemoteCCM, highest defect is
DefErrorCCM for MEP mpid 211
00:52:28: CFM-EVT: Unknown remote mep 213 at domain PROVIDER level 3, vlan

```

```
00:54:46: CFM-EVT: Updated rmep in MIP CCDB, domain PROVIDER level 3, vlan 11
mac 001d.4692.f700 intf Fa0/13
```

To begin fixing the problem, I add MPID 213 back to the service SP_STATIC. ME1 quickly prints a log message to indicate a MEP UP condition, which means valid CCMs were received from MPID 213.

```
! ME1
ethernet cfm domain PROVIDER level 3
  service SP_STATIC vlan 11
    mep mpid 213
```

```
%E_CFM-6-REMOTE_MEP_UP: Continuity Check message is received from a remote
MEP with mpid 213 vlan 11 MA name SP_STATIC domain PROVIDER interface status
Up event code New.
```

However, we don't see RDI clearing on ME3, which indicates something else is still wrong. ME1 is still expecting CCMs for MPID 99 per the configuration, which triggers a DefRemoteCCM alarm.

```
ME1#show ethernet cfm errors domain-id PROVIDER service SP_STATIC
-----
MPID Domain Id                      Mac Address      Type Id
  MA Name                          Reason           Lvl  Age
  Local MEP Info
-----
99  PROVIDER                        0000.0000.0000   Vlan 11
    SP_STATIC                      RMEP missing     3    0s
    MPID: 211 Domain: PROVIDER MA: SP_STATIC
```

To fully fix this problem, we have to remove MPID 99 from ME1's configuration again. This clears the AIS defect for MPID 211 which only occurs once all alarms are clear. We verify by checking the error tables on both ME1 and ME3 to verify, and for good measure, use LBMs to triple check.

```
! ME1
ethernet cfm domain PROVIDER level 3
  service SP_STATIC vlan 11
    no mep mpid 99
```

```
%E_CFM-6-EXIT_AIS: local mep with mpid 211 level 3 VLAN 11 dir U Interface
Fa0/9 exited AIS defect condition
```

```
ME1#show ethernet cfm errors domain-id PROVIDER service SP_STATIC
[no output]
```

```
ME3#show ethernet cfm errors domain-id PROVIDER service SP_STATIC
[no output]
```

```
ME1#ping ethernet mpid 213 domain PROVIDER service SP_STATIC
Type escape sequence to abort.
```

Sending 5 Ethernet CFM loopback messages to 001f.9d0b.1680, timeout is 5 seconds:!!!!
Success rate is 100 percent (5/5), round-trip min/avg/max = 1/2/8 ms

To test another common fault, I will unplug port 9 on ME3. This will affect both the SP and SP_STATIC services bound to that port. ME1 receives CCMs from ME3 that indicate the port has failed, and in return, sets the DefMACstatus alarm. This generally represents an RMEP being down, so seeing that particular error messages makes sense in this case. From CFM's perspective, the service cannot possibly be operational when the UNI port is down.

```
! ME1
%E_CFM-6-REMOTE_MEP_UP: Continuity Check message is received from a remote
MEP with mpid 213 vlan 11 MA name SP_STATIC domain PROVIDER interface status
Down event code PortState.
%E_CFM-6-REMOTE_MEP_UP: Continuity Check message is received from a remote
MEP with mpid 203 vlan 10 MA name SP domain PROVIDER interface status Down
event code PortState.
%E_CFM-3-FAULT_ALARM: A fault has occurred in the network for the local MEP
having mpid 211 vlan 11 for service MA name SP_STATIC with the event code
DefMACstatus.
%E_CFM-3-FAULT_ALARM: A fault has occurred in the network for the local MEP
having mpid 201 vlan 10 for service MA name SP with the event code
DefMACstatus.
```

Examining debugs on ME1, we can see similar output as before. It shows that the current defect is DefMACstatus for ME1, which in turn results in RDI CCMs towards ME3. The RDI CCMs are sent in both SP and SP_STATIC services in ME3 port 9 supported both services.

```
! ME1

```

ME3#show ethernet cfm errors domain-id PROVIDER

MPID Domain Id		Mac Address	Type Id	
MA Name		Reason	Lvl	Age
Local MEP Info				
201	PROVIDER	001d.4692.f700	Vlan 10	
	SP	Receive RDI	3	1s
	MPID: 203 Domain: PROVIDER MA: SP			
211	PROVIDER	001d.4692.f700	Vlan 11	
	SP_STATIC	Receive RDI	3	0s

MPID: 213 Domain: PROVIDER MA: SP_STATIC

Because ME3 saw RDI CCMs from ME1 (identified by brain MAC), we know the problem is on ME1. Again, RDI helps with fault isolation, not necessarily fault identification. Oddly, the ME1 error table doesn't reveal this fault, but the remote MPID details give us a hint. We can see the RMEP is down, which explains why CFM raises the alarm.

```
ME1#show ethernet cfm maintenance-points remote detail mpid 213
Version: IEEE-CFM
MAC Address: 001f.9d0b.1680
Domain Name: PROVIDER
MA Name: SP_STATIC
Level: 3
VLAN: 11
MPID: 213
Incoming Port(s): Port-channel12
CC Lifetime(sec): 5.500
Age of Last CC Message(sec): 0
CC Packet Statistics: 821/0 (Received/Error)
MEP interface status: Down
MEP port status: Up
Receive RDI: FALSE
```

Plugging the cable back in, as expected, resolves the issue quickly. The RDI CCM errors are cleared on ME3, which allows the port to exit AIS status. ME1 displays log message that indicate valid CCMs are received from RMEPs 213 and 203, which cover both services in the PROVIDER domain.

```
! ME3
%E_CFM-6-EXIT_AIS_INT: Interface FastEthernet0/9 exited AIS defect condition
for Down direction
```

```
! ME1
%E_CFM-6-REMOTE_MEP_UP: Continuity Check message is received from a remote
MEP with mpid 213 vlan 11 MA name SP_STATIC domain PROVIDER interface status
Up event code PortState.
%E_CFM-6-REMOTE_MEP_UP: Continuity Check message is received from a remote
MEP with mpid 203 vlan 10 MA name SP domain PROVIDER interface status Up
event code PortState.
```

We can also define MEPs based on ports rather than VLANs. These are considered outward-facing (down) MEPs which means that the CCMs are sent via the wire-side and not the bridge-relay function. Rather than ruin our existing network to demonstrate this, I use a pair of dummy ports on ME1 and ME3 to configure it. Because those ports don't actually communicate, the MEPs won't see one another, but we can view the port-based MEP operation with show and debug commands. For variety, I used a number-based service (rather than a custom string) although this not specific to the port-MEP configuration. I also specify the maximum number of MEPs within a service instance; the default is 100.

```

! ME1 and ME3
ethernet cfm domain PROVIDER level 3
  service number 19 port
  continuity-check
  maximum meps 2

! ME1 only
interface FastEthernet0/7
  ethernet cfm mep domain PROVIDER mpid 291 service number 19

! ME3 only
interface FastEthernet0/7
  ethernet cfm mep domain PROVIDER mpid 293 service number 19

```

Looking at ME3, we check the MEPs configured on port 7. The port-MEP is port-based, not VLAN-based, so I use a dedicated port for this. We can see the direction is “Down”, type is “Port”, CCMs are enabled, and the CFM level is 3. To identify this as a port-MEP, we see the “Id” is “N/A” which means no VLAN.

```

ME3#show ethernet cfm maintenance-points local mep interface fast0/7
Local MEPs:

```

MPID Domain Name		Lvl	MacAddress	Type	CC
Ofld Domain Id		Dir	Port	Id	
MA Name			SrvcInst	Source	
EVC name					
293	PROVIDER	3	001f.9d0b.1689	Port	Y
No	PROVIDER	Down	Fa0/7	none	
	number 19		N/A	Static	
	N/A				

Using debugs for service 19, we can see the CCMs being sent out of this physical interface. This is different from the “UP MEP” where the bridge-relay function used the brain MAC as the source and send CFM frames in towards the CFM level. In this case, packets are being sent out of port 7 every 10 seconds in the “down” direction.

```

ME3#debug ethernet cfm packets domain PROVIDER service number 19
Ethernet CFM level 3 domain PROVIDER service number 19 packet debugging is on

```

```

! ME3
00:14:40: CFM-PKT: Sending Down direction MEP 293 CC message, level 3, cos 7,
port on Fa0/7
00:14:50: CFM-PKT: Sending Down direction MEP 293 CC message, level 3, cos 7,
port on Fa0/7

```

We will create a local SPAN session to capture this in Wireshark to verify the source MAC address. I also reveal both the brain MAC and the port MAC. We can see the source MAC matches that of port 7. I

highlight the maintenance association (MA) short name in the capture since it shows 0x0013, which is 19 in decimal. This is the service number, which could be a text string as we saw earlier.

```

Since the port-MEPs don't have reachability to one another, the RMEPs are never discovered. This technique makes sense on a CE node, potentially, where an entire port is classified uniformly into a single CFM domain and level.

```
ME3#show ethernet cfm maintenance-points remote domain PROVIDER service
number 19
[no output]
```

The last CFM feature we will test is the MEP crosscheck function. This is an exec command that checks the dynamically discovered RMEPs (via CCMs) against the statically configured RMEPs. In the SP_STATIC service, we configured static RMEPs and used CCMs to verify them. This is a recurring/dynamic way to ensure rogue MEPs do not appear in the network and that static MEPs always are present in the network. Cross-check is a one-time, user-initiated method of accomplishing the same thing. Looking at ME3, we can check the cross-check history for all services. Only SP_STATIC shows up since the feature requires static RMEPs configured, otherwise cross-check doesn't know what to test against. The current

status is N/A since the feature has not been used yet. Notice that the show command was very generic and the other services, like number 19 and SP, did not show up; neither have static RMEPs configured.

```
ME3#show ethernet cfm maintenance-points remote crosscheck
```

MPID	Domain Name	Lvl	Type	Id	Mep-Up
	MA Name				
	Local MEP Info				
211	PROVIDER	3	Vlan	11	n/a
	SP_STATIC				
	N/A				

Considering CCMs are already verifying the reachability of MPID 211 from ME3's perspective, the manual cross-check isn't as useful as the automatic CCM method. We will initiate a cross-check on ME3 within the PROVIDER domain and SP_STATIC service. Since the cross-check just uses CCMs anyway, there is nothing to investigate with debugging/Wireshark on the devices. After cross-check completes, a syslog is generated to show that all RMEPs were found with no rogue RMEPs found. The show command also shows "Yes" for each RMEP that was cross-checked.

```
ME3#ethernet cfm mep crosscheck enable domain PROVIDER service SP_STATIC
```

```
00:37:19: %E_CFM-6-CROSSCHECK_SERVICE UP: The device received CC messages from all remote MEPs within a given MA name SP_STATIC in the maintenance domain PROVIDER.
```

```
ME3#show ethernet cfm maintenance-points remote crosscheck
```

MPID	Domain Name	Lvl	Type	Id	Mep-Up
	MA Name				
	Local MEP Info				
211	PROVIDER	3	Vlan	11	Yes
	SP_STATIC				
	N/A				

To temporarily demonstrate the value of cross-check, I will remove the CCM static RMEP checking from ME3 only, while adding a bogus remote MPID. Because ME3 isn't using CCMs to check for this anymore, it won't see an error. ME1 sees no issue with the configuration since it has one RMEP configured and one RMEP discovered. ME3 sees no issue since it isn't actively verifying the presence/absence of MPIDs 99 and 211.

```
! ME3
ethernet cfm domain PROVIDER level 3
service SP_STATIC vlan 11
no continuity-check static rmep
```

```
mep mpid 99
```

```
ME1#show ethernet cfm errors
```

```
[no output]
```

```
ME3#show ethernet cfm errors
```

```
[no output]
```

We can re-run the manual cross-check on ME3 to discover this fault. The cross-check process probes for MPIDs 99 and 211 but only finds 211. MPID 99 was expected, but not seen, within the specific service instance. This raises the AIS condition for the local MPID, and the cross-check show command shows the reachability of each remote MEP.

```
ME3#ethernet cfm mep crosscheck enable domain PROVIDER service SP_STATIC
```

```
00:47:57: %E_CFM-6-ENTER_AIS: local mep with mpid 213 level 3 VLAN 11 dir U  
Interface Fa0/9 enters AIS defect condition
```

```
00:47:57: %E_CFM-3-CROSSCHECK_MEP_MISSING: The device does not receive any CC  
messages from a remote MEP with mpid 99 MA name SP_STATIC that it was  
expecting to be part of the vlan 11 in the domain PROVIDER.
```

```
ME3#show ethernet cfm maintenance-points remote crosscheck
```

MPID	Domain Name	Lvl	Type Id	Mep-Up
	MA Name			
	Local MEP Info			

211	PROVIDER	3	Vlan 11	Yes
	SP_STATIC			
	N/A			
99	PROVIDER	3	Vlan 11	No
	SP_STATIC			
	N/A			

Checking the errors on ME3, we can see there is a remote MEP missing. As seen earlier, we know this is as DefRemoteCCM condition behind the scenes. We also see that since AIS was raised on ME3, the RDI bit is set on CCMs going to ME1, who logs this as a DefRDICCM alarm. ME1's reception of RDI CCMs from ME3 isolates the fault as being local to ME3.

```
ME3#show ethernet cfm errors domain-id PROVIDER service SP_STATIC
```

MPID	Domain Id	Mac Address	Type	Id
	MA Name	Reason	Lvl	Age
	Local MEP Info			

99	PROVIDER	0000.0000.0000	Vlan 11	
	SP_STATIC	RMEP missing	3	182s
MPID: 213 Domain: PROVIDER MA: SP_STATIC				

```
ME1#show ethernet cfm errors domain-id PROVIDER service SP_STATIC
```

```
-----
MPID Domain Id                               Mac Address      Type Id
MA Name                                       Reason           Lvl  Age
Local MEP Info
-----
213  PROVIDER                                001f.9d0b.1680   Vlan 11
     SP_STATIC                               Receive RDI      3    0s
     MPID: 211 Domain: PROVIDER MA: SP_STATIC
-----
```

In this way, cross-check can be useful for a user-initiated check of the network if a platform doesn't support the automatic CCM version. Before continuing, I remove MPID 99 from ME3 and re-enable the static RMEP checks for CCM under the SP_STATIC service instance. This clears all errors.

```
ME3#show ethernet cfm errors domain-id PROVIDER service SP_STATIC
[no output]
```

```
ME3#show ethernet cfm errors domain-id PROVIDER service SP_STATIC
[no output]
```

The configurations for CFM are rolled into the next section since the technologies are complementary.

48.3.2 Ethernet OAM (IEEE 802.3ah)

Although "OAM" is a general term that encompasses many technologies, there actually is a feature called "Ethernet OAM". This is defined in IEEE 802.3ah and is meant mostly for link-monitoring and fault detection. Unlike CFM, which is end-to-end fault management (service-oriented), this is enabled on a per-link basis so there is no flooding of OAM PDUs past a local link. The configuration and verification is much less involved than CFM. The feature is not supported on Etherchannels, so in continuing from the CFM lab, we will enable it on ME2 and ME3 ports 13 and 14. OAM and CFM are not mutually exclusive and both can exist together. The CFM network diagram is shown again for reference. No adjustments to CFM are made.

Enabling the feature is a single command at the link level shown below.

```
! ME2 and ME3
interface range FastEthernet0/13 - 14
  ethernet oam
```

One nice behavior of this feature is that it notifies you when peers are discovered. After configuring it, two syslog messages appear notifying us that the OAM session was created as highlighted in yellow. If we remove the configuration (not shown), we get other syslog messages notifying us about the “down” event as well, shown in green. The “enter session” logs only show up when an OAM neighbor is established, which is similar to most other protocols (IGP, BGP, CFM, etc).

```
! ME2 and ME3
%ETHERNET_OAM-6-ENTER_SESSION: The client on interface Fa0/13 has entered the
OAM session.
%ETHERNET_OAM-6-ENTER_SESSION: The client on interface Fa0/14 has entered the
OAM session.

%ETHERNET_OAM-6-EXIT_SESSION: The client on interface Fa0/13 has left the OAM
session.
%ETHERNET_OAM-6-EXIT_SESSION: The client on interface Fa0/14 has left the OAM
session.
```

We can begin with basic verifications. On ME2, we can see OAM peers on ports 13 and 14 which use their port MAC addresses. This is basically the OAM neighbor table. OUI “00000C” represents Cisco as a vendor, and the list of supported capabilities is shown as well.

```
ME2#show ethernet oam summary
Symbols:          * - Master Loopback State,  # - Slave Loopback State
                  & - Error Block State
Capability codes: L - Link Monitor,  R - Remote Loopback
                  U - Unidirection,  V - Variable Retrieval
```

Local Interface	MAC Address	Remote OUI	Mode	Capability
Fa0/13	001f.9d0b.168f	00000C	active	L
Fa0/14	001f.9d0b.1690	00000C	active	L

To understand how OAM discovery works, we will configure another SPAN session on ME2 to capture traffic on these ports. Once we find the OAM packets, we can see that the source MAC is ME2’s MAC on each of the ports (shown below). The destination MAC is 0180.c200.0002 which, unlike CFM, is processed by the MAC sublayer and cannot be forwarded past a switch that can understand the frame. This is why OAM is link-level; the filtering is done at a very low level in the OSI model. The OAM PDU itself contains many flags the show the link status, each represented as a bit shown in the capture

below. The only thing of interest, at present, is that the link is stable at the both local and remote ends. Because there is only a concept of local/remote, OAM is not supported on half-duplex or shared links; only full-duplex P2P Ethernet links are supported.

```
! ME2
monitor session 2 source interface Fa0/13 - 14
monitor session 2 destination interface Fa0/21 encapsulation replicate
```

.1.. = Remote Stable: True						
OAMPDU code: Information (0x00)						
+ Type: Local Information TLV (0x01)						
+ Type: Remote Information TLV (0x02)						

Debugging received OAM PDUs on ME2 reveals the rate at which packets are sent. This uses the slow protocols ethertype (0x8809, not shown) which is different than other Ethernet protocols with customer ethertypes. The default, the rate is 1 packet per second, and can be reduced to 10 packets per second (100ms interval). We will adjust these timers later. We can prove this with a show command revealing the interface status.

```
ME2#debug ethernet oam packet rx
Ingress packets debugging is on
```

```
! ME2
01:44:26: EOAM RX PAK(Fa0/13): infotlv w/ same revision
01:44:26: EOAM RX PAK(Fa0/14): infotlv w/ same revision
01:44:27: EOAM RX PAK(Fa0/13): infotlv w/ same revision
01:44:27: EOAM RX PAK(Fa0/14): infotlv w/ same revision
01:44:28: EOAM RX PAK(Fa0/13): infotlv w/ same revision
01:44:28: EOAM RX PAK(Fa0/14): infotlv w/ same revision
```

```
ME2#show ethernet oam status interface fast0/13
FastEthernet0/13
General
-----
Admin state:          enabled
Mode:                 active
PDU max rate:         10 packets per second
```

```
PDU min rate:      1 packet per 1 second
Link timeout:      5 seconds
[snip]
```

I will quickly adjust the OAM PDU rate on port 13 on both switches. I will set the min-rate to 2, which means 1 packet per 2 seconds, or a 2 second interval. Debugging received OAM PDUs, we should see two PDUs received on port 14 for every one received on port 13. I also adjust the max-rate which would be used for fast PDU flooding during specific events, halved from 10 pps to 5 pps. The link-timeout is set to 10 seconds as well. In cases the configuration was confusing, the show command clearly details what the numerical inputs accomplish.

```
! ME2 and ME3
interface FastEthernet0/13
  ethernet oam min-rate 2
  ethernet oam max-rate 5
  ethernet oam timeout 10

ME2#show ethernet oam status interface fast0/13
FastEthernet0/13

01:54:20: EOAM RX PAK(Fa0/14): infotlv w/ same revision
```

For more details on the OAM neighbors, we can check the discovery details. Somewhat similar to the MPLS LDP discovery show commands, this shows both local and remote information on a specific interface. From ME2, we see more verbose descriptions of the supported capabilities and OUIs, along with MTU settings and revision information. The PDU revision increments every time a change is made to the discovery PDU, such as active/passive mode (seen later), MTU adjustments, etc. The MTU is 1518 to account for Ethernet (14 bytes) and dot1q (4 bytes) encapsulation. There is no reason to change it in this setup, although the MTU can be mismatched between peers.

```
ME2#show ethernet oam discovery interface fast0/13
```

FastEthernet0/13

Local client

Administrative configurations:

Mode: active
Unidirection: not supported
Link monitor: supported (on)
Remote loopback: not supported
MIB retrieval: not supported
Mtu size: 1518

Vendor(oui): 00000C(cisco)

Administrative configurations:

PDU revision: 0
Mode: active
Unidirection: not supported
Link monitor: supported
Remote loopback: not supported
MIB retrieval: not supported
Mtu size: 1518

The runtime show command is somewhat cryptic but useful. On a particular interface, we can see low-level details regarding some of the bits seen in the OAM PDU above. For example, local stable and remote stable are both “yes”, which corresponds with the Wireshark capture. The state machine at the bottom reveals very low-level details, so I don’t discuss it.

ME2#show ethernet oam runtime interface fast0/13

Runtime Settings:

local_pdu: any
local_mux: fwd
local_par: fwd
local_link_status: OK
local_satisfied: Yes
local_stable: Yes
enter_loopback: No
pdu_cnt: 10
pdu_timer: Running
lost_link_timer: Running

```
loopback_timer: stopped(timeout=2)
remote_state_valid: Yes
remote_stable: Yes
remote_evaluating: 0
remote_rfi: 0
peer version: 3
```

State Machine:

```
-----
sm(ether_oam_port Fa0/13), running yes, state SEND_ANY
Last transition recorded: (remote_state_valid)-> SEND_LOCAL_REMOTE
(local_satisfied)-> SEND_LOCAL_REMOTE_OK (remote_stable)-> SEND_ANY (end)->
INACTIVE (begin)-> FAULT (begin)-> FAULT2 (mode_active)-> ACTIVE_SEND_LOCAL
(remote_state_valid)-> SEND_LOCAL_REMOTE (local_satisfied)->
SEND_LOCAL_REMOTE_OK (remote_stable)-> SEND_ANY
```

Ethernet OAM maintains very detailed statistics as well. The output is very long so I truncate it, but we can see that it tracks many PDU types and events. We will use pieces of this output later during our advanced testing.

```
ME2#show ethernet oam statistics interface fast0/13
```

```
FastEthernet0/13
```

```
Counters:

```

Another minor option involves active and passive modes. Just like LACP, active mode sends OAM PDUs to try and establish a session, while passive mode only responds. At least one of the OAM peers on a link must be active, which is the default mode. I configure ME3 port 13 as passive just for variety. We can verify this from either ME3 or ME2 since the operating mode is carried in the OAM discovery PDUs. I demonstrate both verifications methods below.

```
! ME3
```

```
interface FastEthernet0/13
```

```
    ethernet oam mode passive
```

```
ME3#show ethernet oam discovery interface fast0/13 | begin ^Local
```

```
Local client
```

```
-----
```

Administrative configurations:

```
Mode: passive

```

```
ME2#show ethernet oam discovery interface fast0/13 | begin ^Remote
Remote client
```

```
MAC address: 001f.9d0b.168f
Vendor(oui): 00000C(cisco)
```

Administrative configurations:

```
PDU revision: 1
Mode: passive
Unidirection: not supported
Link monitor: supported
Remote loopback: not supported
MIB retrieval: not supported
Mtu size: 1518
```

Next, we will configure some advanced OAM features. The OAM link-monitor is self-explanatory and is used to check the quality of a given link. It is enabled by default with several tunable parameters. This is also shown under the “status” for a link after the general information (timers, etc) seen earlier. There are low-level details for tuning error thresholds with respect to link quality. When the low-threshold is crossed, an event notification PDU is sent to the OAM peer to notify them of the fault. When the high-threshold is crossed, more extreme action (like disabling an interface) can occur. The defaults are shown below; the low-thresholds are very aggressive so all faults are reported, but all high thresholds are blank so no extreme measures are taken.

```
ME2#show ethernet oam status interface fast0/13 | begin Link_Mon
Link Monitoring
```

```
Status: supported (on)
```

Symbol Period Error

```
Window: 100 x 1048576 symbols
Low threshold: 1 error symbol(s)
High threshold: none
```

Frame Error

```
Window: 10 x 100 milliseconds
Low threshold: 1 error frame(s)
High threshold: none
```

Frame Period Error

Window: 1000 x 10000 frames
Low threshold: 1 error frame(s)
High threshold: none

Frame Seconds Error

Window: 100 x 100 milliseconds
Low threshold: 1 error second(s)
High threshold: none

Receive-Frame CRC Error

Window: 10 x 100 milliseconds
Low threshold: 10 error frame(s)
High threshold: none

Transmit-Frame CRC Error: Not Supported

Simulating these link failures will be very difficult without advanced test equipment, so we will limit our verifications to show commands. Although unnecessary, I configured every possible option just for the sake of doing it once. This does not have to match between OAM peers, so it only configure it on ME3. I also show the context-sensitive help which describes what each fault condition means. The most significant command below is the ability to err-disable an interface that crosses a high threshold, and is highlighted.

```
ME3(config-if)#ethernet oam link-monitor ?
frame           Errored frames in a period measured by time
frame-period    Errored frames in a period measured by number of frames
frame-seconds   Errored frame seconds in a period
high-threshold  Additional high threshold configuration
on              Enable link monitoring on the interface
receive-crc     Received frames with CRC errors in a period
supported       Support link monitoring on the interface
symbol-period   Errored symbols in a period
```

```
! ME3
interface FastEthernet0/13
 ethernet oam link-monitor symbol-period window 32
 ethernet oam link-monitor symbol-period threshold low 12
 ethernet oam link-monitor symbol-period threshold high 24
 ethernet oam link-monitor frame window 200
 ethernet oam link-monitor frame threshold low 2
 ethernet oam link-monitor frame threshold high 50
 ethernet oam link-monitor frame-period window 40000
 ethernet oam link-monitor frame-period threshold low 50
 ethernet oam link-monitor frame-period threshold high 750
 ethernet oam link-monitor frame-seconds window 500
 ethernet oam link-monitor frame-seconds threshold low 35
 ethernet oam link-monitor frame-seconds threshold high 40
 ethernet oam link-monitor receive-crc window 300
```

```
ethernet oam link-monitor receive-crc threshold low 2
ethernet oam link-monitor receive-crc threshold high 10
ethernet oam link-monitor high-threshold action error-disable-interface
```

A brief verification of these minor options is shown below. I don't show the full output, but enough is revealed to see the changes were accepted.

```
ME3#show ethernet oam status interface fast0/13 | begin Link_Mon
Link Monitoring
-----
Status: supported (on)

Symbol Period Error
Window:                32 x 1048576 symbols
Low threshold:         12 error symbol(s)
High threshold:        24 error symbol(s)

Frame Error
Window:                200 x 100 milliseconds
Low threshold:         2 error frame(s)
High threshold:        50 error frame(s)

Frame Period Error
Window:                40000 x 10000 frames
Low threshold:         50 error frame(s)
High threshold:        750 error frame(s)
[snip]
```

Another useful feature is the remote-failure indication (RFI) mechanism. When an OAM speaker discovers a loss of signal (link-fault), dying gasp (unrecoverable condition, such as the peer disabling OAM), or critical-event (vendor specific event), this is communicated to the OAM peer. This particular platform (ME3400) cannot generate link-fault or critical-event PDUs, but can process them upon receipt. It can, however, generate dying-gasp PDUs to show when OAM is removed from an interface, an interface is shutdown, a switch reloads, or some other catastrophic condition that will undoubtedly break OAM. We will configure ME3 port 14 to process all of these events and errdisable the interface as needed.

```
! ME3
interface FastEthernet0/14
 ethernet oam remote-failure link-fault action error-disable-interface
 ethernet oam remote-failure dying-gasp action error-disable-interface
 ethernet oam remote-failure critical-event action error-disable-interface
```

Because the RFI action is errdisable, this implies we could potentially configure auto-recovery for it. The err-disable recovery feature isn't specific to OAM (it supports many applications) but I enable it on ME3

for completeness. If a high-threshold was crossed, the link remains down for 600 seconds (10 minutes) and then the OAM process attempts to recover it.

```
! ME3
errdisable recovery cause oam-remote-failure
errdisable recovery interval 600

ME3#show errdisable detect | include oam
oam-remote-failure      Enabled      port

ME3#show errdisable recovery | exclude Disabled
ErrDisable Reason      Timer Status
-----
oam-remote-failure      Enabled

Timer interval: 600 seconds
```

We can check the statistics for port 14 on ME3 and see that there have been no RFIs so far. This is an indication that the remote peer (ME2 port 14) has not suffered/seen any issues.

```
ME3#show ethernet oam statistics interface fast0/14 | begin Remote_Fault
Remote Faults:
-----
  0 Link Fault records
  0 Dying Gasp records
  0 Critical Event records
```

We can simulate this by removing the OAM configuration from port 14 on ME2 (or shut the interface down, or reload the switch, etc). Before we do that, I enabled state machine (sm) debugging on ME3. We still have Wireshark capturing traffic on ports 13 and 14 as well. ME3 also prints well-written syslog messages which clearly show the problem. The errdisable process shuts down the interface and the line protocol follows.

```
! ME2
interface FastEthernet0/14
 ethernet oam
```

```
! ME3
02:31:45: %ETHERNET_OAM-6-RFI: The client on interface Fa0/14 has received a
remote failure indication from its remote peer(failure reason = remote client
administratively turned off action = error-disable)
02:31:45: %PM-4-ERR_DISABLE: oam-remote-failure error detected on Fa0/14,
putting Fa0/14 in err-disable state
02:31:46: %LINEPROTO-5-UPDOWN: Line protocol on Interface FastEthernet0/14,
changed state to down
02:31:46: %ETHERNET_OAM-6-EXIT_SESSION: The client on interface Fa0/14 has
left the OAM session.
```

In about 5 more minutes (I waited 5 already), the port will attempt to come back online. We can see the cause is due to an OAM RFI, which was the “dying-gasp” message sent from ME2.

```
ME3#show interfaces fast0/14 status
Port      Name      Status      Vlan      Duplex  Speed Type
Fa0/14    TO ME2    err-disabled trunk      auto    auto  10/100BaseTX
```

```
ME3#show errdisable recovery | begin next
Interfaces that will be enabled at the next timeout:
```

Interface	Errdisable reason	Time left(sec)
-----	-----	-----
Fa0/14	oam-remote-failure	319

The debugs reveal nothing of value, other than the port state changing from SEND_ANY to INACTIVE, which indicates a failure of some kind. The syslog messages were more informative, though.

```
ME3#debug ethernet oam sm
State machine changes debugging is on

! ME3
02:31:46:      ether_oam_port Fa0/14: during state SEND_ANY, got event 1(end)
02:31:46: @@@ ether_oam_port Fa0/14: SEND_ANY -> INACTIVE
```

Checking the interface statistics, we can see there was a single dying-gasp received on this interface, along with the timestamp. This is useful in case logging is disabled or for large-scale failures. Notice that there were not any link-fault or critical-event records; we will not be able to generate those in our ME3400 environment.

```
ME3#show ethernet oam statistics interface fast0/14 | begin Remote_Fault
Remote Faults:
-----
 0 Link Fault records
 1 Dying Gasp records
   Total dying gasps      : 1
   Time stamp              : 02:19:41

 0 Critical Event records
```

The capture below shows the final OAM PDU sourced from ME2 port 14 before the port stops running OAM. This is similar to how many IGPs work; when the configuration is removed or the port is gracefully shut down, they may notify their neighbors immediately. The OAM PDU below shows the dying-gasp flag set to 1, which ME3 interprets as an RFI.

No.	Time	Source	Destination	Protocol	Length	Info
	2.715417000	04:c5:a4:53:d8:10	01:80:c2:00:00:02	OAM	60	OAMPDU: Organization Specific

organizationally unique identifier: 00000c (00:00:0c)						

Even by adding “ethernet oam” back onto ME2 port 14, ME3 remains in errdisable until the recovery timer expires. This prevents against constant interface flaps, which can negatively affect STP, REP, G.8032, or any other layer-2 loop prevention mechanism. We could manually shutdown/no shutdown the interface on ME3, or wait until the timer expires and the OAM neighbor forms again. Although not shown here, CFM recovers as well, but I do not show the logs for clarity. I quickly check the OAM status to ensure I see both ports operational.

```
! ME3

02:41:51: %ETHERNET_OAM-6-ENTER_SESSION: The client on interface Fa0/14 has
entered the OAM session.
```

```
ME3#show ethernet oam summary | begin ^Interface
Interface      MAC Address      OUI      Mode      Capability

Fa0/13          04c5.a453.d80f  00000C  active    L
Fa0/14          04c5.a453.d810  00000C  active    L
```

Assuming these RFI and link-monitoring parameters were standard for all OAM links, this would be challenging to configure on many interfaces, especially if the threshold values are tuned regularly. We can define an OAM template to define it once, and then apply it to interfaces. I create a short dummy template on ME3, and then apply it to a dummy interface as an example. This is just a configuration optimization and has the same effect as the things we tested above from an operational perspective. The templates work just like MPLS L2VPN templates, BGP templates, or any other kind of inheritance-based structure in any Cisco CLI.

```
! ME3
template TMP_OAM
ethernet oam link-monitor frame threshold high 1000
```

```
ethernet oam link-monitor high-threshold action error-disable-interface
ethernet oam remote-failure dying-gasp action error-disable-interface
```

```
interface FastEthernet0/3
description DUMMY FOR OAM TEMPLATES
port-type nni
source template TMP_OAM
ethernet oam
```

We know from earlier that checking the interface status will reveal these detailed parameters as shown again below. We can also verify it by looking at the template and seeing that OAM parameters are configured. It also lists the interfaces to which the template is bound.

```
ME3#show ethernet oam status interface fast0/3
FastEthernet0/3

```

The last OAM feature is remote loopback. Like link-monitoring, this is a capability that is exchanged in OAM PDUs. Unlike link-monitoring, it is disabled by default, so I enable it on ME2 and ME3 port 13 with a timeout of 5 seconds, which means that inactivity after 5 seconds will disable the loopback session. Both switches see their peers on port 13 with the “R” capability, which is remote loopback. The feature is disabled by default because it normally makes sense to configure on an as-needed basis for security purposes. The feature must be configured on both ends of a link to operate correctly.

```
! ME2 and ME3
interface FastEthernet0/13
```

```
ethernet oam remote-loopback supported
ethernet oam remote-loopback timeout 5
```

```
ME3#show ethernet oam summary
```

```
Symbols:      * - Master Loopback State, # - Slave Loopback State
              & - Error Block State
Capability codes: L - Link Monitor, R - Remote Loopback
              U - Unidirection, V - Variable Retrieval
```

Local Interface	MAC Address	Remote OUI	Mode	Capability
Fa0/13	04c5.a453.d80f	00000C	active	L R
Fa0/14	04c5.a453.d810	00000C	active	L

```
ME2#show ethernet oam summary
```

```
Symbols:      * - Master Loopback State, # - Slave Loopback State
              & - Error Block State
Capability codes: L - Link Monitor, R - Remote Loopback
              U - Unidirection, V - Variable Retrieval
```

Local Interface	MAC Address	Remote OUI	Mode	Capability
Fa0/13	001f.9d0b.168f	00000C	passive	L R
Fa0/14	001f.9d0b.1690	00000C	active	L

The command also warns us that the command will break traffic flow, as traditional link-level loopbacks would. Notice that only active clients (not passive) can start remote-loopback sessions, so this is a drawback to using OAM passing mode. Since we configured ME3 port 13 as a passive interface, it cannot initiate this session.

```
ME3#ethernet oam remote-loopback start interface fast0/13
```

```
This is a intrusive loopback.
```

```
Therefore, while you test Ethernet OAM MAC connectivity,
you will be unable to pass traffic across that link.
```

```
Proceed with Remote Loopback? [confirm]y
```

```
%Remote loopback must be started from an active Ethernet OAM client.
```

When we issue the same command on ME2, the remote loopback succeeds. The loopback process starts and a syslog message is generated to inform us that ME2 is the “master” of the loopback session.

```
ME2#ethernet oam remote-loopback start interface fast0/13
```

```
This is a intrusive loopback.
```

```
Therefore, while you test Ethernet OAM MAC connectivity,
you will be unable to pass traffic across that link.
```

```
Proceed with Remote Loopback? [confirm]y
```

```
%ETHERNET_OAM-6-LOOPBACK: Interface Fa0/13 has entered the master loopback mode.
```

On ME3, we see a syslog message saying that it entered remote-loopback in slave mode, which means the loopback process is controlled by ME2.

```
! ME3
```

```
%ETHERNET_OAM-6-LOOPBACK: Interface Fa0/13 has entered the slave loopback mode.
```

Ignoring all of the angry syslog messages from CFM telling us the link failed, we can see that OAM loopback is working. Checking the OAM summary on both switches, we can see ME2 identifies its relationship to the OAM peer on port 13 (ME3) as “master loopback”. ME3 does the same except uses “slave loopback”.

```
ME2#show ethernet oam summary
```

```
Symbols:      * - Master Loopback State, # - Slave Loopback State
              & - Error Block State

                  U - Unidirection, V - Variable Retrieval
```

Local Interface	MAC Address	Remote OUI	Mode	Capability
# Fa0/13	04c5.a453.d80f	00000C	active	L R
Fa0/14	04c5.a453.d810	00000C	active	L

We can verify this further by checking the discovery details on both interfaces. ME2, as the master, shows the port in “remote loopback” mode while ME3, as the slave, shows it in “local loopback” mode.

```
ME2#show ethernet oam discovery interface f0/13
```

```
FastEthernet0/13
```

```
Local client
```

```

```

Operational status:

```
Port status:         operational
Loopback status:      local loopback
PDU revision:         7
```

At this point, frames sent from ME2 will be looped back to ME2 via ME3. This is true for all frames that are not OAM PDUs or pause frames. At this point, the looped back frames can be used for measuring latency, jitter, throughput, loss, etc. We can disable the loopback feature using the command below. Syslog messages are generated on both ends to show the loopback being deactivated.

```
ME2#ethernet oam remote-loopback stop interface fast0/13
```

```
%ETHERNET_OAM-6-LOOPBACK: Interface Fa0/13 has exited the master loopback mode.
```

```
! ME3
```

```
%ETHERNET_OAM-6-LOOPBACK: Interface Fa0/13 has exited the slave loopback mode.
```

Additional Reading – Reference configurations "cfm-oam"

48.3.3 Ethernet Local Management Interface (E-LMI) (MEF.16)

Ethernet LMI (E-LMI) is used exclusively between UPE and CE devices within the carrier Ethernet network. This offers the CE access to configuration parameters on the UPE, to include status messages

and error reporting. It interworks seamlessly with CFM and the two are generally configured together. Because CFM is end-to-end, we will configure that as well, and then overlay E-LMI on the UPE-CE link. The OAM network is similar to the CFM/OAM test from earlier, except with some key modifications. ME3 is now a CE device with ME2 as the UPE as shown in the diagram below.

ME2's links to ME3 are the UPE-CE links, each one providing services for a different VLAN. Port 13 uses VLAN 13 only and port 14 uses VLAN 14 only for simplicity. The operator CFM network is largely unchanged, but the all-encompassing CFM domain is a level 7 "customer" network. I could have used the level 3 provider network again, but I wanted it to be somewhat realistic in terms of configuration and naming. The UPE ports are MEPs for the operator's network which offer service for VLAN 10; this is used within the operator's network only. ME1 simulates the remote UPE and has two MEPs within the customer domain, one per customer VLAN (13 and 14). The vast majority of the Ethernet OAM configuration was removed for simplicity and a basic OAM configuration was added back to port 13 only. Although not required, I raise the MIP level on the UPE ports to 7 so that there is no chance the customer uses a level less than 7. This helps guard against cross-connect issues deeper in the network. The MIPs on the UPEs only operate at that level for the specific C-VLANs being serviced. VLAN 10 is allowed on the trunk so that CFM works correctly; if VLAN 10 wasn't available on the UPE, ME2 would not send CCMs since the service cannot work. The CFM configuration is shown below but not discussed.

```
! ME1 and ME3
ethernet cfm domain CUSTOMER level 7
  service number 13 vlan 13
    continuity-check
  service number 14 vlan 14
    continuity-check

! ME1 only

    ethernet cfm mip level 7 vlan 13
    ethernet cfm mep domain OPERATOR mpid 102 service OP1
    ethernet oam

interface FastEthernet0/14
    description TO ME3 (CUSTOMER VLAN 14)
    switchport trunk allowed vlan 10,14
    switchport mode trunk
    ethernet cfm mip level 7 vlan 14
    ethernet cfm mep domain OPERATOR mpid 112 service OP1

```

So far, none of this is new, so I quickly verify the CFM and OAM components. Within the operator network on ME1, we can see 2 remote MEPs. Each one represents a UPE, and there are no errors associated with these MEPs. A pair of Ethernet pings confirms that both are reachable.

```

      MPID: 101 Domain: OPERATOR MA: OP1

```

ME1#show ethernet cfm errors domain-id OPERATOR

[no output]

ME1#ping ethernet mpid 102 domain OPERATOR service OP1

Type escape sequence to abort.

Sending 5 Ethernet CFM loopback messages to 04c5.a453.d800, timeout is 5 seconds:!!!!!!

Success rate is 100 percent (5/5), round-trip min/avg/max = 1/1/1 ms

ME1#ping ethernet mpid 112 domain OPERATOR service OP1

Type escape sequence to abort.

Sending 5 Ethernet CFM loopback messages to 04c5.a453.d800, timeout is 5 seconds:!!!!!!

Success rate is 100 percent (5/5), round-trip min/avg/max = 1/2/8 ms

Next, we will verify that the customer CFM domain is functional following the same steps. ME1 sees two MEPs within the customer domain, each with a different service number. We check for errors in the customer domain, then ping each MEP to ensure reachability. Again, this is just basic CFM verification.

ME1#show ethernet cfm maintenance-points remote domain CUSTOMER

```

```

Next, we will verify the OAM configuration on port 13. OAM PDUs are being exchanged as ME2 sees ME3 as a peer without issue.

```
ME2#show ethernet oam summary
Symbols:          * - Master Loopback State,  # - Slave Loopback State
                  & - Error Block State
Capability codes: L - Link Monitor,    R - Remote Loopback
                  U - Unidirection,    V - Variable Retrieval
```

Local Interface	MAC Address	Remote OUI	Mode	Capability
Fa0/13	001f.9d0b.168f	00000C	active	L

With a functional CFM architecture and OAM between the UPE-CE on a subset of the available services, we will look at E-LMI. For a feature that has limited scope, the configuration is surprisingly involved. The documentation suggests that CFM must be configured (OAM doesn't have to be, though) and the interworking between E-LMI and CFM is required, too. Following that guidance, we configured and verified both CFM and OAM so that the network is prepared for E-LMI. The first step in configuring E-LMI is defining an EVC. This isn't a circuit for carrying traffic per se, but is used to interwork CFM with E-LMI. In this EVC, we specify the OAM protocol of CFM, along with the S-VLAN that has service across the provider network. If the network were larger, this would normally be in a "provider" domain, not an operator one, but the logic is the same. Since VLAN 10 is the service terminated by the operator MEPs on the UPEs (ME1 dummy port and ME2 ports 13 and 14), that is the S-VLAN we specify. The VLAN has transport within the operator domain, and E-LMI needs to know this for CFM interworking. Since we are going to recycle this EVC on two UNI ports, there will be three total UNIs (2 local ports and one remote port). This is a sloppy way to create EVCs as it should be one per "virtual circuit", but I demonstrate this method to show that the UNI count can be changed under EVCs to support multipoint operations.

```
! ME2
ethernet evc EVC_ELMI
uni count 3
oam protocol cfm svlan 10 domain OPERATOR
```

Next, we will enable E-LMI on our UPE interfaces and bind the EVC to a service instance. The service instance maps the C-VLANs to the EVC with the S-VLAN; this is not QinQ or anything like that. This is for signaling only, since the E-LMI between UPE-CE on one end of the network doesn't have visibility to the other side. With CFM, they do. The UNI ID is a required field (string) that is meant to identify this UNI uniquely in the network. I use simple strings "VLAN13" and "VLAN14" for this.

```
! ME3
interface FastEthernet0/13
  ethernet lmi interface
  ethernet uni id VLAN13
  service instance 13 ethernet EVC_ELMI
  ethernet lmi ce-vlan map 13

interface FastEthernet0/14
  ethernet lmi interface
  ethernet uni id VLAN14
  service instance 14 ethernet EVC_ELMI
  ethernet lmi ce-vlan map 14
```

The configuration on the CE side is much simpler. In global configuration, we enable E-LMI for "CE" mode, where "PE" mode is the default. We can also enable E-LMI globally rather than per port, which we do here. We should take care to disable E-LMI explicitly on all other ports that don't need it. The global configuration is probably more appropriate on a UPE with many UNI interfaces, but we can configure it anyway we like.

```
! ME3
ethernet lmi global
ethernet lmi ce

interface range FastEthernet0/7 , FastEthernet0/9, FastEthernet0/11
  no ethernet lmi interface
```

With the configuration complete, we will check the E-LMI status. This is done either in summary form or on a per-EVC basis (detailed). Both outputs are shown below; the "A" stands for active and represents a correct configuration. The detailed version shows additional information like the UNI ID, EVC type, and VLAN ID.

```
ME2#show ethernet lmi evc
```

St	EVC Id	Port
A	EVC_ELMI	Fa0/13,
A		Fa0/14

Key: St=Status, A=Active, P=Partially Active, I=Inactive, ?=Link Down

```
ME2#show ethernet lmi evc detail EVC_ELMI
```

```

EVC Id: EVC_ELMI

  Time since Last Full Report: 00:29:38
  Ether LMI Link Status: Up
  UNI Status: Up
  UNI Id: VLAN14
  CE-VLAN/EVC Map Type: Bundling
  VLAN: 14

EVC Status: Active
EVC Type: Point-to-Point
Remote UNI Count: Configured = 1, Active = 2

UNI Id                UNI Status            Port
-----              -
VLAN13                Up                    Fa0/13

```

We can also verify the EVC status. Notice the EVC-type is MP2MP but we never specified it. This is the result of poor planning; if the UNI count is greater than 2, IOS assumes this is a multipoint service, when in reality we just reused an EVC configuration on multiple ports. There really isn't any connectivity between the two UPE ports based on the C-VLAN mappings, but we accounted for all three UNIs. Checking the UNI count configured/active is a good way to ensure your configuration is correct.

```

ME2#show ethernet service evc id EVC_ELMI detail
EVC ID: EVC_ELMI
EVC Type: MP-MP
UNI Count: Configured = 3, Active = 3
EVC Status: Active
Associated Local Interfaces:
  Interface            CE-Vlans
  FastEthernet0/13     13
  FastEthernet0/14     14

```

Associated UNIs:

UNI-Identifier	Status	Location
VLAN14	Up	Fa0/14
VLAN13	Up	Fa0/13

With the configuration verified, we will explore the discovery process using debugs and Wireshark. On ME2, we enable E-LMI packet debugging; the debugging is verbose but easily read. We can see “status enquiry” messages being received in ports 13 (yellow) and 14 (green) from the CE. The UPE sends “status” messages in reply which is a different message type. Neither message carries any significant information since these are “check” messages. This is the CE’s way of probing the UPE to ensure it is reachable.

```
ME2#debug ethernet lmi packets
Ethernet LMI packets debugging is on
```

```
! ME2

    Data Instance          : Value(0xA)
```

Given the existing SPAN session on ME2, we can see the packets in Wireshark as well. Since Wireshark reveals the MAC addresses, we will confirm them on all 4 ports involved. This helps prove that the E-LMI messages exchanged on a link don’t use the concept of a brain MAC like CFM; the actual link addresses

are used. Additionally, the destination MAC is always 0180.c200.0007, which is unlike CFM where the last 4 bits change depending on the level. The ethertype is always 0x88EE which is specific for E-LMI. Wireshark can understand E-LMI as it parses the frame types and payloads nicely.

```

The status message reply (as a “check”) isn’t interesting, but I show it for completeness. This is sent by the UPE (ME2) back to the CE (ME3) on all ports they share.

No.	Time	Source	Destination	Protocol	Length	Info

Next, we will debug the discovery process on both routers. Unlike CFM and OAM, E-LMI isn't really meant for failure detection. It's more about communicating circuit information between UPE and CE, so when the link fails, nothing interesting happens to E-LMI (no logs, no good debug, etc). The most valuable indication we get from E-LMI that a link is down is a question mark in the summary output. I unplug port 13 on ME3 to break the link temporarily with debug enabled on both ME2 and ME3.

```
ME2#show ethernet lmi evc
St   EVC Id                                     Port
---  ---
?A   EVC_ELM1                                Fa0/13,
A                                         Fa0/14
```

Debugging E-LMI events on both switches for port 13 (only ME2 command is shown), the only significant message we see is shown below. The UPE and CE have slightly different messages with the UPE message being more straightforward.

```
ME2#debug ethernet lmi events interface fast0/13
Ethernet LMI events debugging is on for FastEthernet0/13

! ME2
ELMI Fa0/13 EVENT: Link Down, Async Ignored on this interface

Plugging the cable back in, we receive a lot of debug from both devices. In summary, the devices exchange E-LMI messages to establish their peering relationship again, and we can see some of the update details as well. It shows the number of UNIs configured, number of VLANs, and other information. Wireshark doesn't interpret this information well, so we don't examine the captures for it. Notice that the concept of "full" messages are introduced here. Unlike "check" messages, these actually

contain the EVC status information that a CE would normally require. These are advertised from UPE to CE early in the session formation and sustained via “check” messages.

To see the value of E-LMI, we can introduce some misconfigurations. On the UPE, we will add a bogus VLAN 99 to the C-VLAN mappings associated with the EVC. This doesn't break connectivity, but E-LMI prints an error message on the CE about the mismatch. Essentially, when the PE receives the C-VLAN mappings from the UPE, it compares them against its trunk allowed list. Since only 13 is allowed, the message notes the discrepancy. If you miss the log message, it is stored in the EVC detailed show command as part of the available C-VLANs. This isn't very dangerous because even if VLAN 99 service is offered, the CE isn't using it, so it isn't a big problem.

```
! ME2
interface FastEthernet0/13
 service instance 13 ethernet EVC_ELMI
```

```
ethernet lmi ce-vlan map 13,99
```

```
! ME3
```

```
%ETHER_LMI-6-MISMATCHED_VLAN_NOT_CONFIGURED: VLAN 99 not configured but in  
VLAN mapping for UNI FastEthernet0/13
```

```
ME3#show ethernet lmi evc detail EVC_ELMI interface fast0/13
```

```
EVC Id: EVC_ELMI
```

```
interface FastEthernet0/13
```

```
Time since Last Full Report: 00:01:57
```

```
Ether LMI Link Status: Up
```

```
UNI Status: Up
```

```
UNI Id: VLAN13
```

```
CE-VLAN/EVC Map Type: Bundling
```

```
VLAN: 13,99
```

```
[snip]
```

To test C-VLAN mapping comparison to the local trunk allowed list, we can create the opposite problem also. On ME3, we add VLAN 99 to the trunk allowed list, then remove VLAN 99 from the C-VLAN mappings on the UPE (ME2).

```
! ME3
```

```
interface FastEthernet0/13
```

```
switchport trunk allowed vlan 13,99
```

```
! ME2
```

```
interface FastEthernet0/13
```

```
service instance 13 ethernet EVC_ELMI
```

```
no ethernet lmi ce-vlan map 99
```

The error message is now reversed as VLAN 99 is locally configured on the CE but is not offered as a service by the UPE. This is the more dangerous case because the CE might think VLAN 99 has connectivity but it doesn't. E-LMI is useful since it clearly communicates that VLAN 99 isn't available. Before continuing, I remove VLAN 99 from all switches to restore the network to its baseline.

```
! ME3
```

```
%ETHER_LMI-6-MISMATCHED_VLAN_CONFIGURED: VLAN 99 configured but not in VLAN  
mapping for UNI FastEthernet0/13
```

Another misconfiguration that is probably common (since Cisco doesn't show it in all of their configuration examples) is forgetting to identify a UNI ID to the UPE. I will remove the UNI IDs "VLAN13" and "VLAN14" from the UPE to demonstrate this.

```
! ME2
```

```
interface FastEthernet0/13
```

```
no ethernet uni id VLAN13
```

```
interface FastEthernet0/14
no ethernet uni id VLAN14
```

We will pretend like we never configured the UNI IDs correctly in the first place and begin troubleshooting. Since the CE initiates communication with status enquiry messages, the UPE is expected to respond. However, this cannot occur if a UNI ID is not configured. We can see packets arriving but no responses being sent, and the E-LMI error debugs reveal the issue. A quick look at the sequence numbers in the packet helps confirm the one-way communications since only the “send” value is incrementing from the peer. The CE doesn’t show any errors since it is not aware of a problem; it just sends status enquiry messages over and over.

```
ME2#debug ethernet lmi errors
Ethernet LMI errors debugging is on
```

```
ME2#debug ethernet lmi packets
Ethernet LMI packets debugging is on
```

```
! ME2
```

```

          Data Instance          : Value(0x0)
```

It is interesting to note that the UPE considers the E-LMI sessions “active” in this broken state. This output could be technically true, but it complicates troubleshooting. Even worse, the CE gives no output at all. The lesson here is to rely on debugs when the show commands don’t help.

```
ME2#show ethernet lmi evc
```

St	EVC Id	Port
A	EVC_ELMI	Fa0/13,
A		Fa0/14

Key: St=Status, A=Active, P=Partially Active, I=Inactive, ?=Link Down

```
ME3#show ethernet lmi evc
[no output]
```

Before continuing, I add the UNI IDs back to the UPE ports so E-LMI works properly. Some misconfigurations simply are not allowed by the parser. For example, we used S-VLAN 10 in the operator network within the EVC. If we try to configure a bogus VLAN, the parser rejects it. It checks the CFM domain for the VLAN ID you try to configure to ensure there is a valid CFM service for it within the specified domain. This is very helpful as a protection mechanism.

```
ME2(config-evc)#oam protocol cfm svlan 18 domain OPERATOR
svlan 18 not configured under domain name OPERATOR. First configure it.
```

Two key benefits of E-LMI are that it notifies the CE when EVCs are added and deleted. To test this, I add another pair of operator MEPs between ME1 and ME2 (port 13 UPE only). This will use the operator VLAN 11, and we must add it to the UPE trunk allowed list in order for ME2 to send CCMs for this service instance. This is effectively serving the same purpose of VLAN 10.

```
! ME1 and ME2
ethernet cfm domain OPERATOR level 1
  service OP2 vlan 11
  continuity-check

! ME1 only
interface FastEthernet0/9
  ethernet cfm mep domain OPERATOR mpid 111 service OP2

! ME2 only
interface FastEthernet0/13
  switchport trunk allowed vlan 10,11,13
  ethernet cfm mep domain OPERATOR mpid 111 service OP2
```

We quickly verify this new pair of MEPs has bidirectional reachability. First, we check the MEP listing to see MPID 111 available and servicing VLAN 11 on ME2. Then, we use Ethernet ping to test reachability.

```
ME2#show ethernet cfm maintenance-points remote domain OPERATOR service OP2
```

MPID	Domain Name	MacAddress	IfSt	PtSt
Lvl	Domain ID	Ingress		
RDI	MA Name	Type Id	SrvcInst	
	EVC Name		Age	
	Local MEP Info			
111	OPERATOR	001d.4692.f700	Up	Up
1	OPERATOR	Pol2		
-	OP2	Vlan 11	N/A	
	N/A		3s	

```
MPID: 211 Domain: OPERATOR MA: OP2
```

```
ME2#ping ethernet mpid 111 domain OPERATOR service OP2
Type escape sequence to abort.
Sending 5 Ethernet CFM loopback messages to 001d.4692.f700, timeout is 5
seconds:!!!!!!
Success rate is 100 percent (5/5), round-trip min/avg/max = 1/2/9 ms
```

Next, I will create a dummy EVC that uses this new S-VLAN for signaling. CFM must be operational for this service if we specify CFM as the OAM protocol. The “OAM manager” process is what provides the interworking between CFM and E-LMI, so a functional CFM domain is a prerequisite. We don’t need to change the UNI count as we did before since there are only 2 ports using this EVC (UNI count is 2 by default). Re-using EVCs as I did for VLANs 13 and 14 is bad practice, but technically works. Notice that the EVC below isn’t associated with interfaces yet as we have not applied it.

```
! ME2
ethernet evc EVC_DUMMY
  oam protocol cfm svlan 11 domain OPERATOR

ME2#show ethernet service evc id EVC_DUMMY detail
EVC ID: EVC_DUMMY
EVC Type: P-P
UNI Count: Configured = 2, Active = 2
EVC Status: Active
Associated UNIs:
  UNI-Identifier      Status      Location
  VLAN13              Up          Fa0/13
```

Once we configure it on the UPE port, we can see the EVC bindings are updated. Again we use the bogus VLAN 99 as an offered service for the CE.

```
! ME2
interface FastEthernet0/13
  service instance 99 ethernet EVC_DUMMY
  ethernet lmi ce-vlan map 99

ME2#show ethernet service evc id EVC_DUMMY detail
EVC ID: EVC_DUMMY
EVC Type: P-P
UNI Count: Configured = 2, Active = 2
EVC Status: Active
Associated Local Interfaces:
  Interface      CE-Vlans
  FastEthernet0/13  99
Associated UNIs:
  UNI-Identifier      Status      Location
  VLAN13              Up          Fa0/13
```

Just like last time, VLAN 99 is not configured on ME3's trunk allowed list, so we see a familiar error message. There is a slight difference in the way this information is stored on ME3. This is technically a new EVC, so the EVC table on ME3 is updated to reflect this. The C-VLAN mappings offered by this EVC contain VLANs that are different than the existing EVC, which explains the new table entry. Both EVCs share a UNI ID since that is port-specific, but the actual "virtual circuit" VLAN mappings may differ.

```
! ME3
%ETHER_LMI-6-MISMATCHED_VLAN_NOT_CONFIGURED: VLAN 99 not configured but in
VLAN mapping for UNI FastEthernet0/13
```

```
ME3#show ethernet lmi evc
St  EVC Id                                     Port
---
A   EVC_DUMMY                                Fa0/13
A   EVC_ELMi                                Fa0/13,
A                                     Fa0/14
```

```
ME3#show ethernet lmi evc detail EVC_DUMMY
EVC Id: EVC_DUMMY
interface FastEthernet0/13
  Time since Last Full Report: 00:01:48
  Ether LMI Link Status: Up
  UNI Status: Up
  UNI Id: VLAN13
  CE-VLAN/EVC Map Type: Bundling
  VLAN: 99
  [snip]
```

Debugging E-LMI packets on ME3, we can see this update. Like the E-LMI "hellos", this is a status message, but is the "full" type, not the "check" type. EVC_ELMi is referenced as 0x1 while EVC_DUMMY is referenced as 0x3. Later in the debug, we can see the EVC-to-C-VLAN mappings where the EVC number (0x1 or 0x3) precedes the stanza showing the VLANs. Because this was an addition, we can see that EVC_DUMMY is marked as "new" (green) while EVC_ELMi is "old" (yellow). Different EVCs may have different activity states based on their CFM S-VLAN states. Again, this illustrates why E-LMI is useful for communicating network state to customers, especially if they don't support CFM.

```
ME3#debug ethernet lmi packets interface fast0/13
Ethernet LMI packets debugging is on for FastEthernet0/13
```

```
! ME3

```

To clean up the network, I remove the dummy EVC (not shown). There is no explicit log message, but the fact that the EVC table is stored on the CE qualifies as “informing” the CE of changes in on the UPE. In this way, E-LMI can inform the customers of EVC changes, VLAN mappings, etc. The removal of a deleted EVC is implicit since the full update simply does not include that EVC at all. When a CE receives a full status update, it removes EVCs not listed in the update. This is loosely analogous to LDP implicit label withdrawals, where a new label binding simply overwrites the old one without an explicit withdraw message being issued.

```
ME3#show ethernet lmi evc detail EVC_DUMMY

```

Last, we will examine E-LMI minor optimizations, which include the N393 error counter and T392 polling timer. These timer names are unintuitive and warrant additional explanation/testing. Fortunately, the parser gives us some valuable information.

```
ME2(config-if)#ethernet lmi ?
  interface  Enable Ethernet LMI on this interface
  n393       Error counter
  t392       Polling verification timer
```

The MEF strictly defines these fields in MEF.16-0106 (the output even tells you the specification), their defaults, and their ranges. T392 is called the polling verification timer (PVT) which is 15 seconds by default. This number should be greater than T391, which is the polling timer applicable to the CE; this cannot be adjusted on the UPE. N393 counts the number of consecutive errors, and if the threshold is crossed, E-LMI is considered to be dysfunctional. The default value is 4. N391 counts the number of “check” cycles before requesting a “full” status with a default of 360 (on CE only). I slightly modify both values on ME2 port 13 just for demonstration purposes. To verify it, we can look at the E-LMI interface parameters on both port 13 (customized) and 14 (default) to compare the values. Notice that some other timers are not applicable on PE devices.

```
! ME2
interface FastEthernet0/13
  ethernet lmi t392 20
  ethernet lmi n393 6
```

```
ME2#show ethernet lmi parameters interface fast0/13
E-LMI Parameters for interface FastEthernet0/13
Version : MEF.16-0106
Mode : PE
T391 : NA
T392 : 20
N391 : NA
N393 : 6
```

```
ME2#show ethernet lmi parameters interface fast0/14
E-LMI Parameters for interface FastEthernet0/14
Version : MEF.16-0106
Mode : PE
T391 : NA
T392 : 15
N391 : NA
N393 : 4
```

On the CE, we have a different set of options. N391 (how many consecutive polls before a full status) and T391 (how often to poll) are revealed. We can still count errors, too, as the polling verification timer (T392) is no longer available. I made minor adjustments here as well, then verify it. I also show the defaults from port 14 for comparison.

```
ME3(config-if)#ethernet lmi ?
  interface  Enable Ethernet LMI on this interface
  n391       Polling counter
  n393       Error counter
  t391       Polling timer
```

```

N393 : 4
```

Additional Reading – Reference configurations "cfm-elmi"

48.3.4 Ethernet CFM, OAM, E-LMI, and Y.1731 on CSR1000v (Comprehensive)

This lab tests all of the Ethernet management tools from the previous chapters on the CSR1000v. The main focus of this lab will be a realistic, hierarchical CFM deployment with multiple operators. The service provider maintenance domain spans both operators and provides E-LINE service (EVPL) between three customer sites. CSR5 has a P2P EVPL to CSR1 and CSR2 with EIGRP running inside of it. Each operator, for the sake of not turning every router into a switch, runs a pair of PWs between their edge routers to connect the E-LINE service end-to-end. Ethernet OAM and E-LMI are used between CSR3 (UPE) and CSR2 (CE) for demonstration but are not the focus of the lab. Y.1731 PM and ordinary IP SLA probes are also tested. The diagram is below which shows the operator domains, provider domain, and customer domain. Operator A uses IS-IS and operator B uses OSPF; both of them use LDP and static PWs for their MPLS service delivery. XRv1 and XRv2 are just P routers and their configurations are not shown as they are very basic.

First, we will configure operator A. Since CSR6 and CSR7 are the edge routers in this operator's network, they will have inward-facing (upward) MEPs on their service-instances. This will allow the operator to run CFM within its own network. Since the provider has subcontracted these operators to provide last-mile transport, it will also establish an upward MEP on the service instance that faces the customer only; the provider has no reason to monitor the inter-operator links directly. Since the customer will run CFM as well, the customer-facing service-instance is a level 7 MIP to allow level 7 CFM frames to transit that interface. The inter-operator service-instances are level 4 MIPs to confine lower level traffic but still allow higher level traffic to pass though. Notice that CSR7 does not have the provider domain configured as it does not terminate any MEPs for the provider; the level 4 MIP will allow the provider CCMs to pass. The EVCs also invoke CFM as their OAM protocol. This is mostly relevant for E-LMI but for completeness I add it everywhere. Since the customer (CSR5) has two physical ports connected, each EVPL uses a different C-VLAN tag, which are 3556 (EVC 100) and 3565 (EVC 200) shown below.

```
! CSR6
ethernet cfm ieee
ethernet cfm global
ethernet cfm logging

  cfm mep domain PROVIDER mpid 160
    alarm notification all
  cfm mep domain OPERATOR mpid 160
    alarm notification all
  cfm mip level 7

```

The configuration on CSR7 is similar but lacks the provider domain as there are no MEPs for it. MEP level 4 is used to confine the operator messages (level 1), process the provider (level 4) messages, and pass the customer (level 7) messages. This is what allows CFM to be hierarchical and offer multiple layers of maintenance for different managing organizations.

The routed interfaces below are the MPLS transit links. This is a very basic IS-IS configuration and is not examined in detail. CSR7 is configured similarly (different NET, different IP addresses, etc) but it is not shown for brevity.

```

! CSR6
interface GigabitEthernet2.561
  encapsulation dot1Q 3561
  ip address 131.6.11.6 255.255.255.0
  ip router isis 131
  isis network point-to-point

interface GigabitEthernet2.562
  encapsulation dot1Q 3562
  ip address 131.6.12.6 255.255.255.0
  ip router isis 131
  isis network point-to-point

router isis 131
  net 00.0000.0000.0006.00
  is-type level-2-only
  advertise passive-only
  metric-style wide
  log-adjacency-changes all
  passive-interface Loopback0
  mpls ldp autoconfig

```

Last, we configure the basic L2VPN. Because I used generic naming for the VPN configurations, this syntax is identical on CSR6 and CSR7. I enable L2VPN logging and connect the service-instance to the appropriate PW.

```

! CSR6 and CSR7
l2vpn
  logging pseudowire status

l2vpn xconnect context XC100
  member GigabitEthernet2 service-instance 100
  member pseudowire100

l2vpn xconnect context XC200
  member GigabitEthernet2 service-instance 200
  member pseudowire200

```

Assuming XRv1 and XRv2 have been configured with basic IS-IS and LDP as discussed earlier, the operator's network should be functional. We see several log messages on CSR6 and CSR7 that indicate the PW has come up and the remote operator MEPs have been discovered. This is specific to service number 100 within the operator domain, but identical messages are generated for service number 200 as well.

```

! CSR6
%XCONNECT-5-PW_STATUS: MPLS peer 131.0.0.7 vcid 100, VC state UP
%E_CFM-6-REMOTE_MEP_UP: Continuity Check message is received from a remote
MEP with mpid 107 evc EVC100 MA name number 100 domain OPERATOR interface
status Up event code New.

```

We quickly check the status of the PWs and remote MEPs in case we missed the log messages, beginning with service number 100. The remote MEP also references the PW information, to include the tLDP peer address and VCID. We complete our verification with an Ethernet ping.

```
R6#show l2vpn atom vc vcid 100
```

Interface	Peer ID	VC ID	Service		Status

```

Operator B is different as there are 2 inter-operator routers and 2 UPEs, where in operator A there was only 1 of each. The logic is identical, except that each router only has a single service instance rather than two. I re-use the domain “OPERATOR” at level 1 as well as EVC100 and PW100. Since this information is local to each operator, I was able to quickly build operator B since the configuration is very similar to operator A. The MIP is at level 4 which is identical to operator A, which confines the operator-level CCMs. The OSPF routed interfaces are shown for completeness; like IS-IS in operator A,

there is no IGP complexity in this lab. The PW configuration is identical to what was seen on operator A and two PWs are configured. One PW is between CSR8-CSR10 to service EVC100 while the other is between CSR9-CSR3 to service EVC200.

CSR10 is the UPE for EVC100. It terminates the EVC100 PW and the operator MA. It also terminates the provider MA which should discover the MEPs configured earlier on CSR6. Thus, CSR10 will see MEP 108 in the operator domain (CSR8) and MEP 106 in the provider domain (CSR6). Like CSR6, CSR10 also defines a MIP on this service-instance to keep the provider/operator CCMs away from the customer, yet permit the customer CCMs on ingress.

We can prove this using Ethernet traceroute; recall that this is the only time MIPs use loopback messaging with MEPs. The MIPs at the inter-operator boundary reply to the LTM messages to show the hops between the seams inside of the provider domain. If there were lower-level MIPs within the operator networks, the provider-level traceroute would not have revealed those hops. Before running

the traceroute, I reveal all of the “brain” MAC addresses. Since all of the MEPs have been “UP MEPs” so far, they rely on the bridge-relay function of each CFM bridge and thus do not use the wire-side MAC addresses. I color-code them below and map these colors to the traceroute replies at each hop.

```

Next, we will complete the configuration for EVC200 by configuring CSR3. This is almost identical to CSR10 except services EVC200. I also use a different physical port for the UPE-CE connection so I can support Ethernet OAM as well. The traffic is untagged as this port is connected to the same VLAN (without trunking) as the customer. CSR3 also has a MEP in the operator B and provider domains, so it should behave identically to CSR10 with respect to CFM. Like CSR10, we verify that the PW is up, along with the remote MEPs in both the operator and provider MEGs. We won't verify Ethernet OAM/E-LMI yet as we have not configured the customer devices.

For completeness, I reveal all of the brain MACs within the provider network so that our traceroute verification makes sense. We can see the output is very similar to CSR10 as the last 2 hops are identical, since operator A's network has not changed. The first two hops now represent CSR3 and CSR9, which do not participate in EVC100 at all.

Now that the E-LINE services are fully functional and CFM-managed, we can begin configuring the customers. In the dedicated CFM chapter, I discussed “port MEPs” and configured dummy ports as an example. Here, we will configure and test them on the customer devices. Port MEPs actually make sense here since the customer typically wouldn’t want to configure “UP MEPs” to run CFM with the provider. Port MEPs are always in the down direction, which means the bridge-relay function is not used, and the wire-side MAC address is the source MAC. The CCMs are sent out of the wire-side address as well, so port MEPs are outward-facing (down) MEPs by definition. Port MEPs are also supported on routed ports, and we enable IPv4 processing to prove it. CSR5 uses two different physical interfaces to connect to the UPE which allows us to use port MEPs in the first place. The customer only configures a CFM domain for itself and at the highest level; this guarantees that its CFM frames will be able to transit all MIPs in the provider/operator networks. There are no EVCs configured on the customer sites, and basic EIGRP is enabled to continuously test IP transport over E-LINE.

```
! CSR5
ethernet cfm ieee
ethernet cfm global
ethernet cfm logging
ethernet cfm domain CUSTOMER level 7
  service number 100 port

```

After applying this configuration, we will verify that the customer MEPs came up. We will perform this on CSR5 since it should see both CSR1 and CSR2 as remote MEPs. We also verify the port-level MAC addresses on CSR1 and CSR2 on Gig2; port MEPs use the wire-side MAC addresses for their CCMs, unlike upward-facing MEPs. Again, I use color-coding to make identification easy.

```

R1#show interfaces gigabitEthernet 2 | include bia
    Hardware is CSR vNIC, address is 0050.56a9.1aaa (bia 0050.56a9.1aaa)

R2#show interfaces gigabitEthernet 2 | include bia

```

We can also verify IP connectivity by checking EIGRP neighbors. This ensures that the ESXi virtual networking, PWs, IPv4 ARP, and IP packet transport are all functioning properly. I highlight the “Q-Cnt” column because if EIGRP messages are building in the message queue, this is often a sign of a unicast connectivity issue. Since the queue is empty, we assume EIGRP has converged properly.

```
R5#show eigrp address-family ipv4 neighbors
```

```
EIGRP-IPv4 VR(CUSTOMER) Address-Family Neighbors for AS(125)
```

H	Address	Interface	Hold Uptime	SRTT	RTO	Q	Seq

```

Since the customer isn't even aware of the operator or provider network architectures, it does not see CCMs from either one. They are bounded by level 7 MIPs at the UPEs as a good design practice. We confirm this by debugging on CSR2; notice the CCMs have the "down" direction set, which is different than all other CCM debugging seen so far. This is not adjustable since all port MEPs are down MEPs. Another use for port MEPs in an operator network is on the back-to-back inter-switch links. These can be at level 0 and are like "link-local" MEPs that can be used to test reachability across a very small MEG. The operator level 1 domain, as we have configured it, can span the entire operator's network, and typically uses UP MEPs.

```

interface Gi2
18:54:04.951: CFM-PKT: Sending Down direction MEP 202 CC message, level 7,
cos 7, port on Gi2

```

Now that CFM has been fully verified, we will examine Ethernet OAM between CSR2 (CE) and CSR3 (UPE). The two peers discover one another using OAMPDUs to enter the OAM session. The interface MAC addresses are used and are color-coded below. We see that the “link monitor” capability has been established, which was discussed in detail earlier. This allows the routers to report frame loss, slips, and other important link quality characteristics.

```
R2#show interfaces gigabitEthernet 2 | include bia
Hardware is CSR vNIC, address is 0050.56a9.be8a (bia 0050.56a9.be8a)
```

```
R3#show interfaces gigabitEthernet 2 | include bia
Hardware is CSR vNIC, address is 0050.56a9.8ccf (bia 0050.56a9.8ccf)
```

```
R2#show ethernet oam summary
Symbols:          * - Master Loopback State,  # - Slave Loopback State
                  & - Error Block State
Capability codes: L - Link Monitor,   R - Remote Loopback
                  U - Unidirection,   V - Variable Retrieval
```

Local Interface	MAC Address	Remote OUI	Mode	Capability

Gi3            0050.56a9.be8a  00000C   active  L
```

We will quickly enable “dying-gasp” on CSR3, the UPE. This will err-disable the interface if OAM is removed from the configuration or fails to negotiate a peer. After enabling this feature, we can verify the status of the interface to ensure it is enabled.

```
! CSR3
interface GigabitEthernet3
 ethernet oam remote-failure dying-gasp action error-disable-interface
```

```
R3#show ethernet oam status interface gig 3
GigabitEthernet3
General
-----
Admin state:      enabled
Mode:             active
PDU max rate:     10 packets per second
PDU min rate:     1 packet per 1000 ms
Link timeout:     5000 ms
High threshold action: no action
```

```

Link fault action:      no action
Dying gasp action:     error disable interface
Critical event action: no action

```

I remove Ethernet OAM from CSR2 entirely to test this (not shown). This breaks connectivity to CSR2 entirely even though nothing changed with CFM or MPLS. Using OAM in this way, we can guard against misconfigurations and effectively deny service to customers that are not compliant with OAM policies.

```

! CSR2
%ETHERNET_OAM-6-EXIT_SESSION: The client on interface Gi2 has left the OAM
session.

```

```

! CSR3
%ETHERNET_OAM-6-RFI: The client on interface Gi3 has received a remote
failure indication from its remote peer(failure reason = remote client
administratively turned off action = error-disable)

```

```

R3#show interfaces gig3 | include line_proto
GigabitEthernet3 is administratively down, line protocol is down (err-
disabled)

```

This triggers non-root-cause errors with CFM as well. There are no remote maintenance points since the UNI is down and cannot send/receive CCMs.

```

R3#show ethernet cfm errors

```

Adding Ethernet OAM back to the interface (not shown) does not resolve the problem since the interface is stuck in the err-disabled state. When testing on the ME3400s, we used err-discovery recovery, but this time we will shutdown/no shutdown CSR3's UNI port Gig3. This will clear the err-disable state, allowing Ethernet OAM to form again. Ultimately, this clears the CFM alarms since the MEPs associated with that UNI send/receive CCMs as they normally would.

E-LMI doesn't appear to work well in this setup. Although it worked on the ME-3400s, the CSR1000v (UPE) seems to tunnel the E-LMI status enquiries inside the PW rather than process it locally. We know that the E-LMI ethertype is 0x88EE (yellow), so by using EPC outbound on CSR3 towards the MPLS core, we can confirm this. The E-LMI destination MAC is shown in cyan with CSR2's wire-side MAC address in green, and this is tunneled inside MPLS (grey) which isn't correct. CSR3 does not see the E-LMI packets at all so it can never send a status message; this causes CSR2 to simply time out.

```
R2#debug ethernet lmi packet

```

Cisco's documentation clearly states that, on the ASR1000, E-LMI is not supported on "EoMPLS ports". I assume this includes the EoMPLS access circuit port, which is precisely what we tried to do here. It also states E-LMI is not supported on router ports, which is what we tried to do on CSR2 as well. It seems to me like this feature is best used on actual switches or routers using bridge-domains without any kind of PWs. I will leave the configuration for reference but will not troubleshoot E-LMI further.

Next, we will configure IP SLA probes and Y.1731 PM. First, we configure basic echo and jitter operations on CSR1 and CSR2 towards CSR5, respectively. These operations occur within the customer CFM domain, and as long as NTP is synchronized, the delay probe will yield one-way delay information as well. CSR5 will be the NTP master with CSR1 and CSR2 as NTP clients. Before continuing, we wait for NTP to synchronize. Note: these loopback addresses were advertised via EIGRP but not shown earlier.

```
! CSR5
ntp master
```

```
! CSR1 and CSR2
ntp server 10.0.0.5 minpoll 4 maxpoll 4
ntp source Loopback0
```

```
R5#show ntp status | include sync
Clock is synchronized, stratum 8, reference is 127.127.1.1
```

```
R1#show ntp status | include sync
Clock is synchronized, stratum 9, reference is 10.0.0.5
```

```
R2#show ntp status | include sync
Clock is synchronized, stratum 9, reference is 10.0.0.5
```

First, we will configure the simple Ethernet echo (loopback message) to CSR5. The IP SLA syntax only lets us specify an EVC, VLAN, or port MEP. Since the concept of EVC and VLAN aren't applicable to CSR1, we must select port, which implies there can only be one port within the customer domain. It is for this reason that we cannot use these basic IP SLA probes on CSR5 due to the artificiality of the design.

```
! CSR1
ip sla 15
  ethernet echo mpid 105 domain CUSTOMER port
  cos 3
  threshold 3000
  frequency 5
ip sla schedule 15 life forever start-time now
```

Once we start the probe, we verify that it is successful across the entire service provider network.

```
R1#show ip sla statistics 15
IPSLAs Latest Operation Statistics
```

```
IPSLA operation id: 15
Type of operation: ethernet-echo
  Latest RTT: 7 milliseconds
Latest operation start time: 19:58:35 UTC
Latest operation return code: OK
RTT Values:
  Number Of RTT: 1 RTT Min/Avg/Max: 7/7/7 milliseconds
Number of successes: 701
Number of failures: 0
Operation time to live: Forever
```

For additional debugging, CFM packet debugs also reveal these LBMs. They are sent 5 seconds apart; note that the LBR messages are not revealed in this debug.

```

! CSR1
20:02:25.317: CFM-PKT: Send LM Msg level 7, cos 3, port mac 0050.56a9.dc63 to
interface Gi2
20:02:30.318: CFM-PKT: Send LM Msg level 7, cos 3, port mac 0050.56a9.dc63 to
interface Gi2

```

Next, we configure a basic Ethernet jitter probe on CSR2. This probe sends 10 frames 100 ms apart for a total of 1 second transmission time.

```

! CSR2
ip sla 25
 ethernet jitter mpid 205 domain CUSTOMER port interval 100 num-frames 10
 cos 4
 threshold 3000
 frequency 5
ip sla schedule 25 life forever start-time now

```

Unfortunately, this does not appear to work. I also tried it within the provider/operator networks to no avail. While Y.1731 is not supported on port MEPs or untagged EFPs, this probe is not specific to Y.1731 and should work. I leave it in the configuration for completeness though the router is not even sending probes.

```

R2#show ip sla statistics 25 | include ^Number
Number of successes: 0
Number of failures: 4

```

Since the Ethernet echo operation appears to work, we will use the ethernet-monitor feature to spawn echo probes on CSR3. This will occur inside of the provider CFM domain and use EVC200. For each RMEP inside of this EVC, an Ethernet echo probe is spawned to test reachability. This runs once per minute and is targeting MPID 160, which was gleaned from the remote MEP database. The probe number is 100001 which we learned from the summary show command. We can also see the statistics for this specific probe by using the show command below. This feature appears to work identically in the CSR1000v as it did in the ME3400.

```

! CSR3
ip sla ethernet-monitor 36
 type echo domain PROVIDER evc EVC200
ip sla ethernet-monitor schedule 36 schedule-period 60 start-time now

```

```

R3#show ip sla summary
IPSLAs Latest Operation Summary
Codes: * active, ^ inactive, ~ pending

```

ID	Type	Destination	Stats (ms)	Return Code	Last Run

```
-----
*100001      ethernet-ec Domain:PROVIDER M RTT=13      OK      8 seconds
ago
      ho      pid:160 Evc:EVC20
```

```
R3#show ip sla statistics 100001 | include ^Number
Number of successes: 2
Number of failures: 0
```

Next, we will configure Y.1731 delay and loss measurements. Since 1DM was not supported at all on the ME3400, we attempt to test that here. This only measures one-way delay between two points and the receiving end must be configured explicitly to support it. It also requires NTP synchronization, which we quickly configure first.

```
! CSR6
ntp master
```

```
! CSR7
ntp source Loopback0
ntp server 131.0.0.6 minpoll 4 maxpoll 4
```

```
R6#show ntp status | include sync
Clock is synchronized, stratum 8, reference is 127.127.1.1
```

```
R7#show ntp status | include sync
Clock is synchronized, stratum 9, reference is 131.0.0.6
```

Next, we will configure CSR7 as receive-only for these one-way delay measurement (1DM) frames. We can adjust the distribution buckets just like we did on the ME-3400 switches, as well as adjust some other minor options. Notice that this probe is in “receive” mode and only specified the local (target) MPID. This is loosely analogous to an IP SLA responder, except specific to Y.1731 1DM operations.

```
! CSR7
ip sla 100
  ethernet y1731 delay receive 1DM domain OPERATOR evc EVC100 cos 0 mpid 107
  max-delay 500
  aggregate interval 60
  distribution delay one-way 4 2500,5000,7500,4294967295
  distribution delay-variation one-way 3 2000,4000,4294967295
ip sla schedule 100 life forever start-time now
```

CSR6’s probe looks more standard as it probes MPID 107 from MPID 106. The configuration parameters are the same for consistency.

```
!CSR6
ip sla 100
```

```
ethernet y1731 delay 1DM domain OPERATOR evc EVC100 mpid 107 cos 0 source
mpid 106
max-delay 500
aggregate interval 60
distribution delay one-way 4 2500,5000,7500,4294967295
distribution delay-variation one-way 3 2000,4000,4294967295
ip sla schedule 100 life forever start-time now
```

A quick check of the probe statistics shows that it is successful. Since the frames are one-way, CSR6 initiates while CSR7 completes.

```
R6#show ip sla statistics 100

Debugging on CSR7 reveals similar output. These are not the exact same packets as above, but upon cursory review, appears to indicate receiving the Y.1731 1DM frames and processing them correctly. We

never saw these issues on the ME-3400, and I suspect it has something to do with Y.1731 limitations over EoMPLS/Xconnect.

For testing loss, only LMM is supported in XR version 3.13.2S, which means loss is measured by examining data traffic rather than synthesizing it. For this test, I will probe across both operator networks using the provider MEPs. There is no need to configure anything on CSR10, the target, as that receiver-oriented configuration is specific to 1DM operations. As a result, CSR6 sees both the probe initiations and completions, which makes the probe appear functional.

```

```

To troubleshoot this further, we will look at the raw Y.1731 PM information within the CFM syntax tree. This shows both IP SLA operations in summary form. Both of them appear to be successfully registered as Y.1731 probes.

```
R6#show ethernet cfm pm
```

EPM-ID	SLA-ID	Lvl/Type/ID/Cos/Dir	Src-Mac-address	Dst-Mac-address
0	100	1/XCON/N/A/0/Up	001e.bd69.62bf	001e.49ca.a4bf
1	200	4/XCON/N/A/0/Up	001e.bd69.62bf	001e.e5a8.ffbf

First, we will look at session 0 which is the 1DM probe. We can see that the probe is actively transmitting but not receiving, which appears correct. 1DM frames are being received in the statistics, which is odd because the frames are only flowing in one direction. This may be a cosmetic decision or it may represent some 1DM control-specific response. We also see VSM/VSR messages, which were not discussed earlier. These are vendor-specific messages and replies which vary between vendors. I assume that Cisco is using these messages to report one-way delay measurements from target to source, which is why there are many more VSRs than VSMs. There does not appear to be anything terribly wrong here other than the date stuck in the year 1900.

```

R6#show ethernet cfm pm session detail 0

We also verify the LMM probe across the provider CFM domain to CSR3. There are no vendor-specific exchanges here, and we see LMM/LMR messages being exchanged as expected. The debug revealed this as well, but we can see the counters increment here also. This probe is both TX/RX active as expected.

In summary, Ethernet management functionality works similarly on the CSR1000v as it does on the ME3400. As documented, the router has additional limitations when interworking with EoMPLS, port MEPs, untagged EFPs, and a slew of other non-obvious design constraints. CFM and OAM are the simplest features and “just work”. E-LMI and Y.1731 PM are less forgiving and have additional restrictions; always consult the documentation when configuring complex layer-2 features on routing platforms.

49. Service Provider security best practices (Comprehensive)

Many of the SP security topics listed in the blueprint are independent security topics that are most effective when combined together. I use a large security lab to demonstrate many of these explicitly-defined blueprint topics, along with Cisco’s SP security best practices document. Cisco breaks down their security recommendations into three sections: control plane, management plane, and data plane. Some of the very basic techniques, such as banners, usernames, passwords, and session-timeouts, may not be fully demonstrated since I don’t want to deal with those “timer wasters” every time I access a device for testing. The topology is very large and complex intentionally as there are more than 50 techniques discussed, configured, and tested here. The diagram is shown below, along with all configurations. AS 85 encompasses the routers in “our” network. The ASes on the left are for testing external connectivity. CSR9 has a few VRFs to test L3VPN between CSR3 and CSR7, but this is used only briefly.

Additional Reading – Reference configurations "security"

49.1 Control plane security best practices

1. **Ingress BGP prefix filtering from L3VPN customers:** This refers to basic BGP filtering from L3VPN customers, such as removing bogons, checking for bogus AS paths, etc. The network only has one customer, which includes CSR9 running a pair of VRFs for a basic L3VPN between CSR3 and CSR7 (PEs). Filtering bogons is simple; create a prefix-list based on the current bogon listing and apply it inbound facing the peer. I used two different logical methods for this. The IPv4 bogon list permits the bogons, and the route-map clause denies them. The IPv6 bogon list specifies only the permitted routes (non-bogons), and the route-map clause permits them. This is because the IPv6 bogon list is enormous compared to the IPv4 one, so the opposite logical implementations make sense. The significant difference between inter-SP and customer filtering is that customers often use RFC1918 addressing, so our IPv4 bogon lists at our PEs should not filter this. The show commands for the lists are revealed as the configurations are very long; both lists are configured on both CSR3 and CSR7.

```
R7#show ip prefix-list PL_BOGON_LIST
ip prefix-list PL_BOGON_LIST: 10 entries
  seq 5 permit 0.0.0.0/8 le 32
  seq 15 permit 100.64.0.0/10 le 32
  seq 20 permit 127.0.0.0/8 le 32
  seq 25 permit 169.254.0.0/16 le 32
  seq 35 permit 192.0.0.0/24 le 32
  seq 40 permit 192.0.2.0/24 le 32
```

```

seq 50 permit 198.18.0.0/15 le 32
seq 55 permit 198.51.100.0/24 le 32
seq 60 permit 203.0.113.0/24 le 32
seq 65 permit 224.0.0.0/3 le 32

```

```

R7#show ipv6 prefix-list PL_IPV6_ALLOWED_ROUTES
ipv6 prefix-list PL_IPV6_ALLOWED_ROUTES: 38 entries
  seq 5 deny 2001:DB8::/32 le 128
  seq 10 permit 2001::/32
  [snip]
  seq 190 permit 2C00::/12 le 64

```

We wrap them in a route-map and apply to the peers within the VRF. The configuration is shown from the perspective of CSR7, but CSR3 has an identical configuration, addresses notwithstanding.

```

! CSR7
route-map RM_CUSTOMER_IN deny 10
  match ip address prefix-list PL_BOGON_LIST
route-map RM_CUSTOMER_IN permit 1000

route-map RM_CUSTOMER_IPV6_IN permit 10
  match ipv6 address prefix-list PL_IPV6_ALLOWED_ROUTES

router bgp 85
  address-family ipv4 vrf A
    neighbor 172.16.79.9 route-map RM_CUSTOMER_IN in
  address-family ipv6 vrf A
    neighbor FD00:172:16:79::9 route-map RM_CUSTOMER_IPV6_IN in

```

To verify this configuration, we have some bogon addressing configured within CSR9's test VRFs (192.0.0.91/32 and 192.0.0.92/32, 2FFF::91/128 and 2FFF::92/128) we can use for testing. These are advertised into BGP along with all of the legitimate addresses within the L3VPN (not shown).

```

! CSR9
interface Loopback91
  vrf forwarding A1
  ip address 192.0.0.91 255.255.255.255 secondary
  ipv6 address 2FFF::91/128

interface Loopback92
  vrf forwarding A2
  ip address 192.0.0.92 255.255.255.255 secondary
  ipv6 address 2FFF::92/128

```

Real customer addresses use the 172.16.0.0/16 range. We see that on CSR9, only the 172.16.0.0/16 routes were distributed across the SP. CSR3 and CSR7 specifically say they filtered out those bogon routes. We have full reachability between the proper VPN routes though, but not the bogons.

```

R9#show bgp vpnv4 unicast all | begin Network

A more difficult problem to solve is ensuring that customers don't add bogus AS paths to their AS path lists. Our prefix-based bogon filter cannot prevent this. Customers should be allowed to prepend their own AS for traffic engineering, but prepending other ASes is not permitted. Using advanced regular expressions, we can solve this problem dynamically. Regex parenthesis () means evaluate the expression, then take the value and put it into memory slot 1. The next set of () goes into memory slot 2, etc. If you escape a digit (\1), this references the contents of memory slot 1, and the router can store up to 9 memory slots. On the SP side, use `^([0-9]+)(\1)*$` to match a single AS repeated one or more times. We will define this in an AS-path ACL and integrate it with our route-maps.

```
! CSR3 and CSR7
```

```
ip as-path access-list 85 per ^([0-9]+)(\1)*$
```

How we integrate this new filter with our existing bogon filter depends on the logic of the route-map. With IPv4, we add this to the default permit clause at the end of the route-map so we could add more specific deny clauses later, or possibly exceptions to this prepend security. For IPv6, we include this with our bogon filter to form a Boolean AND. This concludes the SP configuration; it is easy, precise, and dynamic. The AS-path ACL can be reused for any customer regardless of AS, which allows the configuration to scale (no need to make a custom regex per customer).

```
! CSR3 and CSR7
```

```
route-map RM_CUSTOMER_IN permit 1000
```

```
match as-path 85
```

```
route-map RM_CUSTOMER_IPV6_IN permit 10
```

```
match as-path 85
```

I also add some networks to CSR9, some of which are properly prepend, others are not. For IPv4, if the third octet is “97” then the customer prepends incorrectly and the PEs reject it. If the third octet is “99”, the customer prepends properly, and the PE accepts it. This basic configuration is very long but is critical to test the AS-path filter in both directions.

```
! CSR9
interface Loopback91
  vrf forwarding A1
  ip address 192.168.97.91 255.255.255.255 secondary
  ip address 192.168.99.91 255.255.255.255 secondary

interface Loopback92
  vrf forwarding A2
  ip address 192.168.99.92 255.255.255.255 secondary
  ip address 192.168.97.92 255.255.255.255 secondary

  address-family ipv6 vrf A2
    neighbor FD00:172:16:79::7 route-map RM_IPV6_OUT out
```

We can verify this by checking VPN routes on CSR9. The “97” routes never make it across the PE network and are filtered due to their AS paths. The “99” networks are advertised across the VPN since they appear in opposite VRFs. We also see the provider’s AS path has overwritten all instances of the local AS thanks to the “as-override” feature on CSR3 and CSR7.

```
R9#show bgp vpnv4 unicast all 192.168.64.0/18 longer-prefixes | begin Network

2. **Intra-AS filtering:** Control unnecessarily advertisement of iBGP prefixes via RRs if needed. This is less of a technical feature as it is a policy control mechanism. The intent is to use standard BGP filtering techniques within an AS, likely on the RRs, to not distribute all information to all routers, unless necessary. This may include using the XE BGP RR-group or XR RT-retention features on RRs to conserve memory or limit route propagation. There is no demonstration for this task as no new technologies or methods are introduced. The general logic of this recommendation is to only advertise routes across the network to devices that actually require reachability.

3. **Baseline the routing table:** This technique helps detect routing anomalies over time. This is more of a policy decision than a technical one, with the exception of the “route profile” utility. This is not available in XR and appears to only support IPv4 at this time in XE. I enable this feature on CSR2 as a demonstration. The intent is to monitor changes in the routing table over 5 second intervals. The first column (change/interval) says “I saw this many changes in the last 5 seconds”. The remaining columns are tallies for the number of times an event occurred. In this example, there were 6 intervals whereby zero new prefixes were added, for example. This output shows a stable routing table.

```
! CSR2
ip route profile
```

```
R2#show ip route profile
IP routing table change statistics:
Frequency of changes in a 5 second sampling interval
```

```
-----
Change/   Fwd-path  Prefix   Nexthop  Pathcount  Prefix
interval change    add      change   change     refresh
-----
```

```

0          6          6          6          6          6
1          0          0          0          0          0
2          0          0          0          0          0
3          0          0          0          0          0
4          0          0          0          0          0
5          0          0          0          0          0
10         0          0          0          0          0
[snip]

```

If I clear IS-IS and BGP several times (not shown), we can see several routing changes in this profile. This doesn't tell us which routes changed, but it gives a rough estimate. It helps diagnose instability when dealing with thousands of routes. In this output, we see that within a single 5 second interval, we had between 10 and 14 fwd-path changes. We also had several prefix additions and path count changes at one time as well. Towards the end of the convergence cycle, we had a single route fwd-path change in its own 5 second interval. Low numbers in these columns, like 1 or 2, indicate normal, occasional reconvergence events. If the numbers are growing very quickly, or the row index (change/interval) is very large, chances are there is a routing issue or extreme churn. Notice that the "0" row has the highest values because most of the time, the routing table remains stable.

```

R2#show ip route profile
IP routing table change statistics:
Frequency of changes in a 5 second sampling interval

```

```

-----
Change/  Fwd-path  Prefix  Nexthop  Pathcount  Prefix

[snip]

```

4. **Authenticate routing updates for BGP:** This prevents attacker from inserting information. On XE boxes, only a single MD5 password is allowed, but XR has support for key-chains. In order for the key-chains to work, you must specify the crypto method of HMAC-MD5, otherwise BGP will not send the hash. I made a rotating key-chain to change keys each month (with a 2 minute overlap) for the rest of calendar year 2015. For brevity, I only show the months of July and August below; this shows the rollover configuration logic. Note that this method requires the devices to have time synchronization.

```

! XRv1, XRv2, and XRv4
key chain KC_BGP_AUTH

```

```

key 7
  accept-lifetime 23:58:00 june 30 2015 23:59:59 july 31 2015
  key-string password 080B796230262E322B
  send-lifetime 23:58:00 june 30 2015 23:59:59 july 31 2015
  cryptographic-algorithm HMAC-MD5
key 8
  accept-lifetime 23:58:00 july 31 2015 23:59:59 august 31 2015
  key-string password 106F3C3E30242634272113
  send-lifetime 23:58:00 july 31 2015 23:59:59 august 31 2015
  cryptographic-algorithm HMAC-MD5

```

Using the key-chain is considered enhanced authentication (EA) and is not supported by XE, so I only enabled it between XR routers for extra security. On XR, I have a separate session-group for the XE routers that only uses the password method. Using inheritance of session-groups, we use the same basic iBGP session parameters for all iBGP peers, but use different authentication methods between platforms based on their capabilities. The application of the session-group to all peers is not shown. Other peers have been configured with the proper key-chains and passwords as required.

```

! XRv4
session-group IBGP_XE
  use session-group IBGP_BASIC
  password encrypted 072D067C71282C313F

session-group IBGP_XR
  use session-group IBGP_BASIC
  keychain KC_BGP_AUTH

```

We can verify MD5 authentication by looking at the TCP information. XR has a succinct way of displaying this; we can see a brief of all BGP peers along with their authentication type. All XE routers use MD5 while the XR routers use EA (which is MD5-based as well).

```

RP/0/0/CPU0:XRv4#show tcp authentication database checkpoint | include BGP
0x40002fd8  8.8.8.8          BGP  0x60000000  MD5  0x00004cb8
0x40002e38  4.4.4.4          BGP  0x60000000  MD5  0x00004cb8
0x40002dd8  12.12.12.12     BGP  0x60000000  EA   0x0002680d
0x40002e98  11.11.11.11     BGP  0x60000000  EA   0x0002680d
0x40002e58  7.7.7.7         BGP  0x60000000  MD5  0x00004cb8
0x40002e18  3.3.3.3         BGP  0x60000000  MD5  0x00004cb8
0x40002df8  10.10.10.10     BGP  0x60000000  MD5  0x00004cb8

```

There are some restrictions on EA. Specifically, **you must specify a time range**, or else you get this error. Even if that time-range is infinite, it must be configured, which is different than some other protocols that rely on key-chains for authentication.

```
! XRv4
```

```
IP-TCP-3-EAOPT_SEND_NOKEY : No active send-key for key-chain 'KC_BGP_CUST'
for the Enhanced Authentication option to send to peer 10.11.14.14, error -
'Key Chain Server Process' detected the 'fatal' condition 'No key available'
```

Additionally, the key ID must fit into 6 bits (63 or less), or else you get this error when committing the candidate configuration. If using monthly keys, I recommend using the month number (1 through 12). If using weekly keys, use the week number (1 through 52).

```
! XRv4
Send key-id 100 for keychain 'KC_BGP_CUST' (peer 10.11.14.11) greater than
Enhanced Authentication max(63)
```

On XE, we can check the TCP database for the TCP control block (TCB) for a specific BGP session, then check the negotiated option flags. MD5 is option 19 for TCP (this number isn't revealed here), so ensure any firewalls/data-plane filters in the network do not drop packets carrying this option.

```
R2#show tcp brief | include 11\11
7F5318233800 2.2.2.2.179 11.11.11.11.25413 ESTAB
```

```
R2#show tcp tcb 7F5318233800 | include ^Option
Option Flags: nagle, path mtu capable, md5, Retrans timeout
```

5. **Limit BGP prefix counts:** This feature prevents a flood of BGP routes from an external peer. This is enabled using the “maximum-prefix” command in XE and XR and is AFI-specific. It sets a limit on how many prefixes can be received from a BGP peer, along with a warning threshold and restart timer. If the restart timer is not set, the neighbor will never advertise any routes until it is hard-cleared. Below are the configurations and verifications for IPv4 and IPv6 across XR and XE. We will apply these changes inside the eBGP AFI templates so that it automatically applies to all eBGP peers.

```
! XRv1
router bgp 85
  af-group AF_IPV4_EBGP address-family ipv4 unicast
    maximum-prefix 100 50
  af-group AF_IPV6_EBGP address-family ipv6 unicast
    maximum-prefix 100 50
```

```
RP/0/0/CPU0:XRv1#show bgp ipv6 unicast neighbors 10.1.3.13 | utility egrep
'For Address|Maximum|warn'
```

```
For Address Family: IPv4 Unicast
  Maximum prefixes allowed 100
  Threshold for warning message 50%, restart interval 0 min
For Address Family: IPv6 Unicast
  Maximum prefixes allowed 100
  Threshold for warning message 50%, restart interval 0 min
```

```
! CSR8
router bgp 85
```

```

template peer-policy IPV4_EBGP
  maximum-prefix 100 50
template peer-policy IPV6_EBGP
  maximum-prefix 100 50

R8#show bgp ipv4 unicast neighbors 10.1.8.1 | include For_add|Maximum|warn
For address family: IPv4 Unicast
  Maximum prefixes allowed 100
  Threshold for warning message 50%
For address family: IPv6 Unicast
  Maximum prefixes allowed 100
  Threshold for warning message 50%

```

If we temporarily reduce CSR8's maximum to 4 towards CSR1, the prefix limit will be exceeded. CSR8 makes it very clear with several BGP logs, first stating the prefix limit (this number 4 is actually encoded in the message sent to the offending peer, CSR1), then notifying the peer of its transgression. We can see that this applies to both IPv4 and IPv6 AFIs in this example.

```

! CSR1
router bgp 85
  address-family ipv4
    neighbor 10.1.8.1 maximum-prefix 4
  address-family ipv6
    neighbor 10.1.8.1 maximum-prefix 4

%BGP-3-MAXPFEXCEED: Number of prefixes received from 10.1.8.1 (afi 0): 17
exceeds limit 4
%BGP-3-NOTIFICATION: sent to neighbor 10.1.8.1 6/1 (Maximum Number of
Prefixes Reached) 7 bytes 00010100 000004
%BGP-5-ADJCHANGE: neighbor 10.1.8.1 Down Peer over prefix limit
%BGP_SESSION-5-ADJCHANGE: neighbor 10.1.8.1 IPv6 Unicast topology base
removed from session Peer over prefix limit
%BGP_SESSION-5-ADJCHANGE: neighbor 10.1.8.1 IPv4 Unicast topology base
removed from session Peer over prefix limit

```

BGP also makes it very clear in other show commands in case the log messages are not seen. As an added benefit, the command tells us how to remedy the situation. This could be automatic if we configured a restart timer, which is not the default.

```

R8#show bgp ipv4 unicast neighbors 10.1.8.1 | begin : IPv4 Unicast
For address family: IPv4 Unicast
[snip]
Peer had exceeded the max. no. of prefixes configured.
Maximum prefixes allowed 4
Threshold for warning message 75%
Reduce the no. of prefix and clear ip bgp 10.1.8.1 to restore peering

```

From CSR1's perspective, we see some logs that indicate a capability change. This is CSR8 signaling to CSR1 that it no longer supports IPv4 unicast, which means CSR1 will never advertise any IPv4 unicast prefixes, either. That is why the hard-clear is required to fix this issue, since the session itself has been poisoned as a protection mechanism. CSR8's BGP OPEN message no longer contains the IPv4 unicast capability towards CSR1 at all, which guarantees that IPv4 unicast prefixes cannot be received. CSR1 also shows this when we examine the negotiated capabilities with CSR8. CSR8 is no longer willing to run IPv4 unicast with CSR1 after having been told it was advertising too many prefixes.

```
! CSR1
%BGP_SESSION-5-ADJCHANGE: neighbor 10.1.8.8 IPv4 Unicast topology base
removed from session BGP Notification received
%BGP_SESSION-5-ADJCHANGE: neighbor 10.1.8.8 IPv4 Unicast topology base
removed from session Capability changed
```

```
R1#show bgp ipv4 unicast neighbors 10.1.8.8 | section capabilities
Neighbor capabilities:
  Route refresh: advertised and received(new)
  Four-octets ASN Capability: advertised and received
  Address family IPv4 Unicast: advertised
  Address family IPv6 Unicast: advertised and received
  Enhanced Refresh Capability: advertised and received
```

Before continuing, I fixed the issue by setting maximum back to 100 and clearing the session (not shown). A quick verification shows everything is working again as expected.

```
R1#show bgp ipv4 unicast neighbors 10.1.8.8 | section capabilities
Neighbor capabilities:
  Route refresh: advertised and received(new)
  Four-octets ASN Capability: advertised and received
  Address family IPv4 Unicast: advertised and received
  Address family IPv6 Unicast: advertised and received
  Enhanced Refresh Capability: advertised and received
```

```
R1#show bgp ipv4 unicast neighbors 10.1.8.8 advertised-routes | begin Network
      Network      Next Hop      Metric LocPrf Weight Path
*>  1.10.0.0/16      0.0.0.0          0         32768 ?
*>  1.11.0.0/16      0.0.0.0          0         32768 ?
*>  1.12.0.0/16      0.0.0.0          0         32768 ?
[snip]
```

6. **Ingress BGP prefix filtering from peer ISPs:** This is used for removal of bogons, RFC 1918 addressing, etc. This was covered in detail when we examined ingress L3VPN customer BGP filtering. The only difference is that the bogon prefix-lists will contain RFC1918 addressing this time as these should not be leaked between SPs (exceptions may include architectures like Inter-AS MPLS Option C). The application is still the same; inbound route-map or route-policy facing the peer while wrapping a prefix-list or prefix-set to deny bogons. Because this is a general best practice, I prefer using peer-policy

templates or AF-groups to modularize the configuration. Although not mentioned in this document, I suggest only advertising locally-assigned addresses out, assuming the local AS is not a transit AS. The AS 85 outbound policies simply permit 85.0.0.0/8 for simplicity; using the regex “^\$” would also be effective as it would permit local routes only. The XE configuration can be trickier because when running IPv6 over an IPv4 BGP session, next-hops must be manually modified, which means a different outbound route-map per peer. The commands to enable peer-policy or AF-group inheritance are not shown. Use the normal BGP show commands to see if the proper routes are entering and exiting the network, as we saw earlier. The verification process is the same and is not repeated for brevity. The RPL/route-map names are self-explanatory so their contents are not displayed.

```
! Basic XR policy
router bgp 85
  af-group AF_IPV4_EBGP address-family ipv4 unicast
    route-policy RPL_EBGP_IN in
    route-policy RPL_85_ONLY out

  af-group AF_IPV6_EBGP address-family ipv6 unicast
    route-policy RPL_EBGP_IPV6_IN in
    route-policy RPL_EBGP_IPV6_OUT out

  neighbor 10.1.3.13
    address-family ipv4 unicast
      use af-group AF_IPV4_EBGP
    address-family ipv6 unicast
      use af-group AF_IPV6_EBGP

! Basic XE policy

    neighbor 10.8.9.9 inherit peer-policy IPV6_EBGP
    neighbor 10.1.8.1 route-map RM_EBGP_OUT_R1 out ! Needed to adjust NHOP
    neighbor 10.8.9.9 route-map RM_EBGP_OUT_R9 out ! Needed to adjust NHOP
```

7. **BGP dampening:** This is used to penalize unstable routes which prevents non-stop flapping and BGP instability. Unlike throttling mechanisms, this feature will actually break reachability to prefixes that

are deemed sufficiently unstable. Several parameters can be configured to tune how aggressively BGP dampens routes, but if no parameters are specified, default values are used. The formula is as follows:

$$\text{max-penalty} = \text{reuse-limit} * 2^{(\text{max-suppress-time}/\text{half-life})}$$

For variety, XRv1 and CSR8 have BGP dampening enabled for IPv4 and IPv6 AFs with default parameters. I do not believe there is a way to see the default parameters in XR, but XE shows it. These parameters are the same for all AFs.

```
! XRv1
router bgp 85
  address-family ipv4 unicast
    bgp dampening
  address-family ipv6 unicast
    bgp dampening
```

```
! CSR8
router bgp 85
  address-family ipv4
    bgp dampening
  address-family ipv6
    bgp dampening
```

```
R8#show bgp ipv4 unicast dampening parameters
```

```
dampening 15 750 2000 60 (DEFAULT)
Half-life time       : 15 mins      Decay Time          : 2320 secs
Max suppress penalty: 12000         Max suppress time: 60 mins
Suppress penalty    : 2000         Reuse penalty       : 750
```

Two important values are not listed here nor are they configurable. When a route flaps, the router imposes a penalty value of 1,000 to that route. If the route only has an attribute change, the penalty is 500. If the route has enough of these “changes” to surpass the “suppress penalty”, the route is dampened. This value is a threshold that, once crossed, means BGP considers the route unusable and won’t consider it for best-path selection. For example, if a route flaps twice and has its MED changed once within a short time, the penalty will be around 2500, enough to trip the threshold.

The reason I say “around” 2500 is because of the half-life. This value determines how quickly the penalty fades away (like radioactive decay). A 15 minute half-life means that after 15 minutes, the penalty will become half of its current value. Therefore, a penalty of 2500 will take 15 minutes to reach 1250. The max-penalty and max-suppress-time are upper bounds on how “bad” a route can be. After 12,000 max-penalty points, the counter stops incrementing, but the route still has to stay dampened until the penalty goes back below the suppress reuse penalty threshold. The max-suppress-time is input to the formula that ultimately determines the max-penalty value. Being the numerator in the fraction, a larger max-suppress-time implies a potentially higher max-penalty. A shorter half-life means the route gets “forgiven” more rapidly, but be careful to ensure the math resolves to sensible values. Once the penalty

falls below the re-use penalty (750), the route can be re-used, like a falling-threshold. Once it falls below half of the re-use penalty (375), all penalty points are removed.

On CSR4, we will configure custom dampening parameters in a route-map. We could also specify specific prefixes, communities, AS-paths, etc. to apply dampening only to certain routes. In this case, we apply dampening only to routes originating inside AS 1.1 using an AS-path ACL. Let's say we want to use the default parameters except we want the half life to be very slow, making "bad" routes take longer to re-enter the BGP table as best-path candidates. In this case, we select a half-life that is very large (slow), so much so that the math is invalid. It does not make sense for the max-penalty to be less than the suppress-penalty; if it were, then routes would never be suppressed, since they could only be penalized up to 1880 points when 2000 is required for dampening.

```
! CSR4
ip as-path access-list 1 permit _65537$

route-map RM_DAMP_FROM_AS_1DOT1 permit 10
  match as-path 1
  set dampening 45 750 2000 60

router bgp 85
  address-family ipv4
    bgp dampening route-map RM_DAMP_FROM_AS_1DOT1
  address-family ipv6
    bgp dampening route-map RM_DAMP_FROM_AS_1DOT1
```

We evaluate the formula: $\text{max-penalty} = 750 * 2^{(60/45)} = 750 * 2^{(2.5)} = 750 * \sim 2.51 \sim 1880$

The router notifies us of our folly with a log message, and also removes our invalid BGP dampening configuration. These logs are important because once the configuration is removed, it may not be obvious why the router is rejecting the configuration.

```
! CSR4
%BGP-5-DAMPENING LOW MAX PENALTY: Maximum penalty (1880) is less than
suppress penalty (2000), Dampening is OFF
```

There is also a hard-limit on the max-penalty of 20,000. It is possible to exceed this value using a different set of invalid parameters. This would occur if we were trying to have a very fast turnover using a small half-life. If the half-life is only 5 minutes with all other parameters set to their defaults, we get another message telling us our math is still wrong but for the opposite reason.

```
! CSR4
route-map RM_DAMP_FROM_AS_1DOT1 permit 10
  set dampening 5 750 2000 60

router bgp 85
```

```

address-family ipv4
  bgp dampening route-map RM_DAMP_FROM_AS_1DOT1
address-family ipv6
  bgp dampening route-map RM_DAMP_FROM_AS_1DOT1

```

We evaluate the formula as follows: $\text{max-penalty} = 750 * 2^{(60/5)} = 750 * 2^{(12)} = 750 * 4096 = 3072000$

```
! CSR4
```

```
%BGP-5-DAMPENING_HIGH_MAX_PENALTY: Maximum penalty (3072000) is more than
allowed maximum (20000). Dampening is OFF
```

Clearly, BGP dampening is a tricky topic given the math involved. Let's say our design goal is to have a more reactive policy. We want a faster half life (more forgiving), but we also want routes suppressed more quickly. We should reduce the half-life, max-suppress-timer, and suppress-penalty, and potentially increase the re-use penalty. Now, the routes are penalized sooner at 1,500 penalty points, but are also allowed back into the RIB sooner when their penalty drops under 1,000. The half life will be very fast at 5 minutes, with no route being suppressed longer than 15 minutes. This gives us an 8,000 point max penalty, which is greater than the suppress penalty of 1500 and less than the max-penalty hard-limit of 20,000. Again, this upper-bound on the max-penalty does not appear configurable.

```
! CSR4
```

```
route-map RM_DAMP_FROM_AS_1DOT1 permit 10
  set dampening 5 1000 1500 15
```

```
router bgp 85
  address-family ipv4
    bgp dampening route-map RM_DAMP_FROM_AS_1DOT1
  address-family ipv6
    bgp dampening route-map RM_DAMP_FROM_AS_1DOT1

```

We evaluate the formula as follows: $\text{max-penalty} = 1000 * 2^{(15/5)} = 1000 * 2^{(3)} = 1000 * 8 = 8000$

We don't see a log message because we did not cause an error. The parameters for dampening also include the route-map entry from which the settings were derived. We can see the max penalty of 8,000 also to check our math. The benefit of not using prefix-lists in these route-maps means they can be recycled between AFs. Communities and AS-paths are typically not AF-dependent and are good options for filtering due to their flexibility and reusability.

```

R4#show bgp ipv4 unicast dampening parameters
dampening 5 1000 1500 15 (route-map RM_DAMP_FROM_AS_1DOT1 10)
Half-life time       : 5 mins      Decay Time          : 720 secs
Max suppress penalty: 8000         Max suppress time: 15 mins
Suppress penalty    : 1500        Reuse penalty       : 1000

```

Next, we configure XRv2 with the same dampening parameters to ensure XR rejects the invalid options and accepts the valid options. XR is smart in that it will not let you commit an invalid configuration. XR also doesn't tell you the result of the math, unlike XE, so you must know the formula. The verbiage hints that our max-suppress is too low, which is true. These hints can be helpful for fixing the errors.

```
! XRv2
route-policy RPL_BGP_DAMPENING_FROM_AS_9DOT13
  if as-path originates-from '589837' then
    set dampening halflife 45 suppress 2000 reuse 750 max-suppress 60
  endif
end-policy

router bgp 85
  address-family ipv4 unicast
    bgp dampening route-policy RPL_BGP_DAMPENING_FROM_AS_9DOT13

% Failed to commit [snip]

!!% Verify failed for policy: Policy [RPL_BGP_DAMPENING_FROM_AS_9DOT13] uses
an invalid argument in the statement 'set dampening halflife 45 suppress 2000
reuse 750 max-suppress 60' at the bgp dampening-dflt attach point. Policy
attempted to set invalid values for dampening parameters. Inconsistent
dampening parameters. Decrease half-life, or increase suppress, max-
suppress, or reuse-penalty.
```

Let's use another invalid example as a quick test by causing the max-penalty to be greater than 20,000. The verbiage is a little different because its telling us the max-suppress is too high.

```
! XRv2
route-policy RPL_BGP_DAMPENING_FROM_AS_9DOT13
  if as-path originates-from '589837' then
    set dampening halflife 5 suppress 2000 reuse 750 max-suppress 60
  endif
end-policy

router bgp 85
  address-family ipv4 unicast
    bgp dampening route-policy RPL_BGP_DAMPENING_FROM_AS_9DOT13

% Failed to commit [snip]

!!% Verify failed for policy: Policy [RPL_BGP_DAMPENING_FROM_AS_9DOT13] uses
an invalid argument in the statement 'set dampening halflife 5 suppress 2000
reuse 750 max-suppress 60' at the bgp dampening-dflt attach point. Policy
attempted to set invalid values for dampening parameters. Inconsistent
dampening parameters. Decrease max-suppress or reuse-penalty, or increase
half-life.
```

We add a corrected example at the end and ensure XR accepts the change.

```
! XRv2
route-policy RPL_BGP_DAMPENING_FROM_AS_9DOT13
  if as-path originates-from '589837' then
    set dampening halflife 5 suppress 1500 reuse 1000 max-suppress 15
  endif
end-policy

router bgp 85
  address-family ipv4 unicast
    bgp dampening route-policy RPL_BGP_DAMPENING_FROM_AS_9DOT13
```

Next, we should test the feature to make sure it works. We will use the route 9.14.0.0/16 for testing since both XRv1 and XRv2 prefer the eBGP paths via AS 9.13 (always verify this first). The two routers have varying dampening parameters, though, so flapping this route will have different effects. Recall that XRv1 uses the default parameters while XRv2 has a custom policy. We will examine both together.

```
RP/0/0/CPU0:XRv1#show bgp ipv4 unicast 9.14.0.0/16 brief | begin Network
  Network      Next Hop      Metric LocPrf Weight Path
* i9.14.0.0/16  8.8.8.8          0      100      0 589837 ?
*>              10.1.3.13          0      100      0 589837 ?
```

```

* i            11.11.11.11      100      0 589837 ?
```

I delete the IP prefix from CSR9, which causes BGP to withdraw it (not shown). Both XRv1 and XRv2 mark it with “history” to note that this prefix is currently not reachable, but we are remembering it so we can keep a tally of its penalty points. BGP cannot simply purge this prefix from memory or else it would have no mechanism to track the incurring penalties.

```

```

Network	From	Flaps	Duration	Reuse	Path
*> 9.14.0.0/16	10.2.9.9	1	00:01:50		589837 ?

When the route comes back, there is no issue because the suppress penalties of 2000 (XRv1) and 1500 (XRv2) have not been breached (not shown). The route has penalty points but the suppress penalty has not been breached, so both XRv1 and XRv2 can consider the route for best-path selection. If we flap the route again (also not shown), XRv1 still accepts the route, because a few seconds of half life means that 1000 plus a little less than 1000 is a little less than 2000. XRv1 is not currently dampening this prefix despite flapping twice. XRv1 needs to wait about 4 minutes before reusing this prefix.

```

RP/0/0/CPU0:XRv1#show bgp ipv4 unicast flap-statistics 9.14.0.0/16 | begin
Network

```

Network	From	Flaps	Duration	Reuse	Path
*> 9.14.0.0/16	10.1.3.13	2	00:04:01		589837 ?

```

RP/0/0/CPU0:XRv1#show bgp ipv4 unicast dampened-paths

```

[no output]

XRv2, however, dampens the route as it exceeded the 1500 penalty ($\sim 2000 > 1500$). The BGP entry now contains additional dampening information to include timers as to when the route will be usable again (that is to say, its penalty drops beneath 1000). XRv2's dampening statistics also show a "d" for dampening path, while earlier we saw a ">" symbol indicating XRv2 selected it as a best-path. Notice that XRv2 selects the iBGP path via XRv1 as its best path. This is the expected behavior since dampened paths are not candidates in the best-path selection algorithm.

```

For variety, we will quickly repeat the same test on CSR4 and CSR8 for IPv6 AF using the prefix 2001:1C00:B::/48 on CSR1. Recall that CSR4 has the customized parameter set while CSR8 uses the defaults. CSR8 should behave like XRv1 and CSR4 should behave like XRv2 from the previous example. Before starting, we quickly verify the best paths to the route and ensure it is via CSR1 on both routers.

```

Bringing the route back on CSR1 (also not shown) causes both routers to re-install it as a best path. Both routers record the flap statistics within the prefix, so that even as a best-path, the administrator is aware of the potentially instability.

Flapping the route again on CSR1 (not shown) causes CSR4 to suppress the route while CSR8 is still accepting it. In this situation, CSR4 picks an iBGP best path via CSR8 to reach this prefix. **Dampening never applies to internal prefixes, but only external and confed-external.** Because CSR8 has not dampened the iBGP prefix, this is a valid alternative path. This is the same thing we observed on XRv2 when it used the iBGP path via XRv1 as a backup. In about 3 minutes, the eBGP path will be usable again. This is based on the half-time and how long it takes for the penalty to fall below the reuse threshold.

```

```
R8#show bgp ipv6 unicast dampening dampened-paths
[no output]
```

8. **BGP neighbor logging:** This allows the SP to track unstable BGP peers. Neighbor logging is very basic feature and is enabled by default on XE and XR BGP implementations. We have seen several examples of BGP logging thus far and it should be obvious as to why this is desirable. In a production environment, sending them to a syslog server for analysis is most effective. Below are snippets to disable this feature; I do not apply this configuration anywhere since BGP neighbor logging is valuable.

```
! XE
router bgp 85
  no bgp log-neighbor-changes

! XR
router bgp 85
  bgp log neighbor changes disable
```

9. **TTL-security:** This feature is applied on external and confed-external peers to prevent remote attacks against the BGP peering process. This is a simple but highly intelligent mechanism. BGP differentiates between "connected" and "process-learned" (OSPF, EIGRP, RIP, static, etc) routes when forming eBGP neighbors. By default, only connected routes can be used for eBGP peers. Some documentation suggests that if you configure eBGP peerings between loopbacks you need to increase the session TTL using "ebgp-multihop". This is not true; TTL=1 is sufficient to reach the remote neighbor (assuming the two routers are connected), but we need to tell BGP to specifically use process-learned

routes for it. This is what “disable-connected-check” does in XE and “ignore-connected-check” does in XR. Here is a quick summary of TTL-security behavior when configured in concert with other features.

eBGP peers with no fancy options: TTL=1 and will only look at connected routes

eBGP peers + disable-connected-check: TTL=1 and will also look at connected or process

eBGP peers + ebgp-multihop x: TTL=x and also look at connected or process

eBGP peers + TTL-security hops 1: TTL=255 and only looking at connected routes

eBGP peers + TTL-security hops x: TTL=255 and also looking at process routes

eBGP peers + TTL-security hops 1 + disable-connected-check: TTL=255 and also looking at connected or process routes. This is the most secure way to configure eBGP across two connected router loopbacks.

The expected received TTL must be at least 255-x with TTL security, since x is the max hop count. If “ttl-security hops 1” is configured on one side, at a minimum, the remote peer must send eBGP packets with TTL=255. This can be accomplished by also enabling TTL-security or using eBGP multihop; the remote peer must use one of these two mechanisms or else the session will not form. In XR, the TTL-security hop count is always 1 and cannot be changed. I have enabled TTL security on all eBGP peers. A sample of router configurations is shown below.

```
! XRv1
router bgp 85
  neighbor 10.1.3.13
    ttl-security

! CSR8
router bgp 85
  neighbor 10.8.9.9 ttl-security hops 1
```

We can verify the feature is functional by checking the neighbor status. XR doesn’t give as much information but it’s still a valid verification. Also notice that XE says the eBGP peer is configured for connected checks, which implies “disable-connected-check” was not configured. Since there is no need for process-learned routes to form this eBGP session, we omit this feature; this adds security.

```
RP/0/0/CPU0:XRv1#show bgp ipv4 unicast neighbors 10.1.3.13 | include TTL
TTL security is configured
```

```
R8#show bgp ipv4 unicast neighbors 10.8.9.9 | include hop|TTL
  External BGP neighbor may be up to 1 hop away.
  External BGP neighbor configured for connected checks (single-hop no-
  disable-connected-check)
Connection is ECN Disabled, Minimum incoming TTL 254, Outgoing TTL 255
```

10. BGP policy accounting (PA): This feature is used to account for traffic using communities or other matching mechanisms. The configuration is very similar to QPPB, which I use on XRv1 and CSR4 later to show other security features. We will configure BGP PA on XRv2 and CSR8 for this

demonstration. CSR10 will set the community value on specific prefixes when it injects them into BGP; I use a route-map and network statement for this and the configuration is shown later. On ingress, the ASBRs will check their BGP table-policies for specific communities, and then set the traffic-index marker, of which there are 64 total. CEF will account for packets/bytes based on the traffic-index and we can get a quick summary of those statistics using BGP PA. My policy is as follows:

- a. Routes with community 85:1024 are placed in traffic-index 1
- b. Routes with community 85:2048 are placed in traffic-index 2
- c. Routes with community 85:4096 are placed in traffic-index 4

First, we will configure CSR10 to originate IPv4 and IPv6 routes into BGP with some communities. The same prefixes will be used for QPPB later, and we are using 85.19.8.0/21 and 2001:85:19::/63 with communities set to 85:1024 and 85:2048, respectively.

```
! CSR10
route-map RM_SET_COMM permit 10
  set community 85:1024

route-map RM_SET_COMM_IPV6 permit 10
  set community 85:2048

router bgp 85
  address-family ipv4
    network 85.19.8.0 mask 255.255.248.0 route-map RM_SET_COMM
  address-family ipv6
    network 2001:85:19::/63 route-map RM_SET_COMM_IPV6
```

A quick check of the BGP tables on the ASBRs to ensure the communities were properly communicated is warranted. Rather than checking the prefix, I will query based on communities. This ensures that communities are being exchanged between iBGP peers (default behavior for XR but not XE).

```

RP/0/0/CPU0:XRv2#show bgp ipv6 unicast community 85:2048 | begin Network
      Network      Next Hop      Metric LocPrf Weight Path
*>i2001:85:19::/63  10.10.10.10      0      100      0 i
* i                10.10.10.10      0      100      0 i

```

Next, we configure the policies used by BGP. These are XE route-maps or XR RPLs that are applied under the BGP table-map, just like QPPB. We will start with CSR8 first.

```

! CSR8
ip community-list standard COML_TRAF_IDX1 permit 85:1024
ip community-list standard COML_TRAF_IDX2 permit 85:2048
ip community-list standard COML_TRAF_IDX4 permit 85:4096

route-map RM_BGP_PA per 10
  match community COML_TRAF_IDX1
  set traffic-index 1
route-map RM_BGP_PA per 20
  match community COML_TRAF_IDX2
  set traffic-index 2
route-map RM_BGP_PA per 30
  match community COML_TRAF_IDX4
  set traffic-index 4

router bgp 85
  address-family ipv4
    table-map RM_BGP_PA
  address-family ipv6
    table-map RM_BGP_PA

interface GigabitEthernet2.518
  bgp-policy accounting input

interface GigabitEthernet2.589
  bgp-policy accounting input

```

We should verify that the interface-level commands were accepted. The output is strange in that it says BGP policy mapping is disabled, then in the next line, says it is an input feature. I will assume that the feature was enabled correctly and continue despite the odd output.

```

R8#show ip interface gig2.518 | include BGP
  BGP Policy Mapping is disabled
  Input features: BGP Policy Map, Access List, uRPF, MCI Check

R8#show ip interface gig2.589 | include BGP
  BGP Policy Mapping is disabled
  Input features: BGP Policy Map, uRPF, MCI Check

```

The tricky part is the order of operations: if the routes were installed in the FIB before the PA policy is applied, you must “clear ip route” so they are re-added. Below is a before-and-after example of this behavior. For simplicity, I refresh all IPv4 routes rather than target the specific one; both methods work.

```
R8#show ip cef 85.19.8.0 detail
85.19.8.0/21, epoch 2, flags [rib only nolabel, rib defined all labels]
  recursive via 10.10.10.10
    nexthop 85.6.8.6 GigabitEthernet2.568 label 6006
```

```
R8#clear ip route *
```

```
R8#show ip cef 85.19.8.0 detail
85.19.8.0/21, epoch 2, flags [rib only nolabel, rib defined all labels]
  BGP: traffic_index 1
  recursive via 10.10.10.10
    nexthop 85.6.8.6 GigabitEthernet2.568 label 6006
```

Like QPPB, XE does not appear to support BGP PA for IPv6. Notice there is no traffic-index applied for the IPv6 traffic, even after a RIB/FIB refresh. We will test this in the data-plane later just to make sure it isn't a cosmetic issue with the show command.

```
R8#show ipv6 cef 2001:85:19::/63 detail
2001:85:19::/63, epoch 0, flags [rib defined all labels]
  recursive via 10.10.10.10 label 10007
    nexthop 85.6.8.6 GigabitEthernet2.568 label 6006
```

```
R8#clear ipv6 route *
```

```
R8#show ipv6 cef 2001:85:19::/63 detail
2001:85:19::/63, epoch 0, flags [rib defined all labels]
  recursive via 10.10.10.10 label 10007
    nexthop 85.6.8.6 GigabitEthernet2.568 label 6006
```

We can check the counters by looking at CEF policy statistics. Right now we see no statistics on either external interface.

```
R8#show cef interface gig2.518 policy-statistics
GigabitEthernet2.518 is up (if_number 14)
  Corresponding hwidb fast_if_number 13
  Corresponding hwidb firstsw->if_number 8
  BGP based Policy accounting on input is enabled
```

Index	Packets	Bytes
1	0	0
2	0	0
3	0	0
4	0	0

```

R8#show cef interface gig2.589 policy-statistics
GigabitEthernet2.589 is up (if_number 15)
  Corresponding hwidb fast_if_number 13
  Corresponding hwidb firstsw->if_number 8
  BGP based Policy accounting on input is enabled
Index      Packets      Bytes
  1         0         0
  2         0         0
  3         0         0
  4         0         0

```

We will test from CSR9 to start, but we must ensure CSR9 is routing through CSR8 to reach 85.19.8.0.

```

R9#show ip route 85.19.8.0
Routing entry for 85.19.8.0/21
  Known via "bgp 589837", distance 20, metric 0
  Tag 85, type external
  Last update from 10.8.9.8 13:54:00 ago
  Routing Descriptor Blocks:
  * 10.8.9.8, from 10.8.9.8, 13:54:00 ago
    Route metric is 0, traffic share count is 1
    AS Hops 1
    Route tag 85
    MPLS label: none

```

```

R9#ping 85.19.8.1 source 9.15.9.9 repeat 50
[snip]
Success rate is 100 percent (50/50), round-trip min/avg/max = 1/18/27 ms

```

CSR8's CEF process has accounted for 50 packets and 5000 total bytes (the pings were 100 bytes each) within traffic-index 1 as expected. Note that CEF does not account for layer 2 encapsulation with BGP PA. Because this is per-interface, the link between CSR8 and CSR1 has not logged any packets yet.

```

R8#show cef interface gig2.589 policy-statistics
GigabitEthernet2.589 is up (if_number 15)
  Corresponding hwidb fast_if_number 13
  Corresponding hwidb firstsw->if_number 8
  BGP based Policy accounting on input is enabled
Index      Packets      Bytes
  1        50       5000
  2         0         0
  3         0         0
  4         0         0

```

```

R8#show cef interface gig2.518 policy-statistics
GigabitEthernet2.518 is up (if_number 14)
  Corresponding hwidb fast_if_number 13

```

```

Corresponding hwidb firstsw->if_number 8
BGP based Policy accounting on input is enabled
Index          Packets          Bytes
1              0              0
2              0              0
3              0              0
4              0              0

```

A quick test from CSR1 (ensuring it routes through CSR8) shows that the traffic is also classified but kept separate. This time we send twice as many packets of double the size, so the total byte count should be 4 times what it was in the previous test.

```

R1#show ip route 85.19.8.0
Routing entry for 85.19.8.0/21
  Known via "bgp 1.1", distance 20, metric 0
  Tag 85, type external
  Last update from 10.1.8.8 00:00:03 ago
  Routing Descriptor Blocks:
  * 10.1.8.8, from 10.1.8.8, 00:00:03 ago
    Route metric is 0, traffic share count is 1
    AS Hops 1
    Route tag 85
    MPLS label: none

```

```

R1#ping 85.19.8.1 source 1.14.1.1 repeat 100 size 200
[snip]
Success rate is 100 percent (100/100), round-trip min/avg/max = 1/38/157 ms

```

We verify the statistics again. Nothing new came from CSR9, but the link to CSR1 now accounts for those new packets.

```

R8#show cef interface gig2.589 policy-statistics
GigabitEthernet2.589 is up (if_number 15)
  Corresponding hwidb fast_if_number 13
  Corresponding hwidb firstsw->if_number 8
  BGP based Policy accounting on input is enabled
Index          Packets          Bytes
1              50             5000
2              0              0
3              0              0
4              0              0

```

```

  Corresponding hwidb fast_if_number 13
  Corresponding hwidb firstsw->if_number 8
  BGP based Policy accounting on input is enabled
Index          Packets          Bytes

```

1	100	20000
2	0	0
3	0	0
4	0	0

We also want to test IPv6 quickly to see if it's actually supported. A quick test from CSR9 shows that it is not, so I won't belabor it. CSR9 is routing through CSR8 as expected, but when traffic is sent, nothing is captured by BGP PA.

```
R9#show ipv6 route 2001:85:19::1
Routing entry for 2001:85:19::/63
  Known via "bgp 589837", distance 20, metric 0, type external
  Route count is 1/1, share count 0
  Routing paths:
    FD00:10:8:9::8
      MPLS label: nolabel
      Last updated 14:01:59 ago
```

```
R9#ping 2001:85:19::1 source 2001:9000:A::9 repeat 20 size 300
[snip]
Success rate is 100 percent (20/20), round-trip min/avg/max = 15/30/93 ms
```

```
R8#show cef interface gig2.589 policy-statistics
GigabitEthernet2.589 is up (if_number 15)
  Corresponding hwidb fast_if_number 13
  Corresponding hwidb firstsw->if_number 8
  BGP based Policy accounting on input is enabled
```

Index	Packets	Bytes
1	50	5000
2	0	0
3	0	0
4	0	0

Next, we examine the BGP PA feature on XRv2. The configuration is similar to XE except we use RPL instead with inline community sets for brevity/variety. We also need to be more specific at the interface level to determine whether we are doing source or destination accounting. If you don't specify in XE, it assumes destination, while source is another option. For XR, you must specify source or destination, and you can select both concurrently. XRv supports IPv6 and explicitly uses separate PA IPv4/v6 commands.

```
! XRv2
route-policy RPL_BGP_PA
  if community matches-every (85:1024) then
    set traffic-index 1
  elseif community matches-every (85:2048) then
    set traffic-index 2
  elseif community matches-every (85:4096) then
    set traffic-index 4
```

```

    else
        pass
    endif
end-policy

router bgp 85
  address-family ipv4 unicast
    table-policy RPL_BGP_PA
  address-family ipv6 unicast
    table-policy RPL_BGP_PA

interface GigabitEthernet0/0/0/0.529
  ipv4 bgp policy accounting input destination-accounting
  ipv6 bgp policy accounting input destination-accounting

```

We will verify that it has been enabled for both IPv4 and IPv6 on XRv2's external interface. We also verify the current BGP policy statistics for this interface, and we expect no matches. XR simply doesn't show anything if nothing appears, versus XE that shows a list of zeroes per bucket. Our final initial verification is ensuring the traffic-indices were applied properly. XR shows the traffic-index mappings in the RIB where XE shows this in the FIB. This validates our BGP PA RPL configuration; if we did not see these traffic-index markings in the RIB, we should clear the routing table so everything gets refreshed, depending on the order of operations.

```
RP/0/0/CPU0:XRv2#show ipv4 interface gig0/0/0/0.529 | utility egrep
'BGP|Desti'
```

```
IP Input BGP policy accounting is configured
Input-Source is Disabled, Input-Destination is Enabled
```

```
RP/0/0/CPU0:XRv2#show ipv6 interface gig0/0/0/0.529 | utility egrep
'BGP|Desti'
```

```
IP Input BGP policy accounting is configured
Input-Source is Disabled, Input-Destination is Enabled
```

```
RP/0/0/CPU0:XRv2#show cef ipv6 interface gig0/0/0/0.529 bgp-policy-statistics
GigabitEthernet0/0/0/0.529 is UP
```

```
Input BGP policy accounting on dst IP address enabled
  buckets      packets      bytes
```

```
RP/0/0/CPU0:XRv2#show cef interface gig0/0/0/0.529 bgp-policy-statistics
GigabitEthernet0/0/0/0.529 is UP
```

```
Input BGP policy accounting on dst IP address enabled
  buckets      packets      bytes
```

```

```

```
Known via "bgp 85", distance 200, metric 0, type internal, Traffic Index 2
```

```
Routing Descriptor Blocks
```

```
::ffff:10.10.10.10, from ::ffff:2.2.2.2
```

[snip]

```
RP/0/0/CPU0:XRv2#show route ipv4 85.19.8.0
Routing entry for 85.19.8.0/21
  Known via "bgp 85", distance 200, metric 0, type internal, Traffic Index 1
  Routing Descriptor Blocks
    10.10.10.10, from 2.2.2.2
    [snip]
```

Next, we ensure CSR9 is routing through XRv2 to reach 2001:85:19::0/63. We may need to clear BGP with CSR8 so that the oldest route is learned from XRv2. CSR9 sends traffic to this destination successfully.

```
R9#show ipv6 route 2001:85:19::0
Routing entry for 2001:85:19::/63
  Known via "bgp 589837", distance 20, metric 0, type external
  Route count is 1/1, share count 0
  Routing paths:
    FE80::12, GigabitEthernet2.529
      MPLS label: nolabel
      Last updated 00:00:08 ago
```

```
R9#ping 2001:85:19::1 source 2001:9000:C::9 repeat 20 size 400
[snip]
Success rate is 100 percent (20/20), round-trip min/avg/max = 5/75/252 ms
```

When we check the CEF counters on XRv2, we see the packets properly measured. In XE, we saw nothing, likely because BGP policy features like PA and QPPB are not supported for IPv6 at all. The IPv6 traffic was supposed to end up in bucket 2, and it did.

```
RP/0/0/CPU0:XRv2#show cef ipv6 interface gig0/0/0/0.529 bgp-policy-statistics
GigabitEthernet0/0/0/0.529 is UP
Input BGP policy accounting on dst IP address enabled
  buckets      packets      bytes
  2           20           8000
```

We will quickly test IPv4 also, which also appears to work. Once we validate CSR9 is routing through XRv2, we send some traffic from CSR9 and measure it on XRv2. The traffic is in bucket 1 as expected.

```
R9#show ip route 85.19.8.0
Routing entry for 85.19.8.0/21
  Known via "bgp 589837", distance 20, metric 0
  Tag 85, type external
  Last update from 10.2.9.12 00:08:37 ago
  Routing Descriptor Blocks:
    * 10.2.9.12, from 10.2.9.12, 00:08:37 ago
      Route metric is 0, traffic share count is 1
```

```
AS Hops 1
Route tag 85
MPLS label: none
```

```
R9#ping 85.19.8.1 source 9.14.9.9 repeat 15 size 150
[snip]
Success rate is 100 percent (15/15), round-trip min/avg/max = 2/13/146 ms
```

```
RP/0/0/CPU0:XRv2#show cef interface gig0/0/0/0.529 bgp-policy-statistics
GigabitEthernet0/0/0/0.529 is UP
Input BGP policy accounting on dst IP address enabled
  buckets      packets      bytes
  1           15          2250
```

11. **LDP and IGP security:** LDP and IGP peers should be authenticated for the same reasons described in the BGP authentication section. Interestingly, XR does not support key-chains for LDP authentication but does for BGP. XE is the opposite, so LDP peers between CSRs use key chains where exceptions are made (single passwords) for XR peers. CSR2 is a good example. The key chain is not shown for brevity. LDP security is discussed in detail in the LDP section.

```
! CSR2
mpls ldp password required
mpls ldp password fallback KC_LDP_AUTH
mpls ldp neighbor 14.14.14.14 password XR_LDP_AUTH
```

A quick way to check MD5 authentication on LDP peers is to look at the detailed LDP neighbor output, and specifically at the TCP connection information. We can also use the manual TCP method shown earlier in the BGP section. I show it again for reference.

```
R2#show mpls ldp neighbor detail | include TCP
TCP connection: 14.14.14.14.37949 - 2.2.2.2.646; MD5 on
TCP connection: 6.6.6.6.47235 - 2.2.2.2.646; MD5 on
TCP connection: 7.7.7.7.35620 - 2.2.2.2.646; MD5 on
TCP connection: 10.10.10.10.21470 - 2.2.2.2.646; MD5 on
```

```
R2#show tcp brief | include 6\.6
TCB          Local Address      Foreign Address      (state)
7F5323C2CE68 2.2.2.2.646             6.6.6.6.47235       ESTAB
```

```
R2#show tcp tcb 7F5323C2CE68 | include ^Option|MD5
Option Flags: non-blocking reads, non-blocking writes,
MD5 lossless password switchover, Retrans timeout
```

XR configuration is very straightforward. Under the general neighbor stanza, just enable a password and it applies to all neighbors. Again, additional LDP authentication testing is done in the LDP section.

```
mpls ldp
neighbor
password encrypted 033C69342A2B11736F3C2D2D
```

XR verification is similar exception we don't need to use the "detail" keyword.

```
RP/0/0/CPU0:XRv4#show mpls ldp neighbor | include MD5
TCP connection: 2.2.2.2:646 - 14.14.14.14:37949; MD5 on
TCP connection: 3.3.3.3:646 - 14.14.14.14:38725; MD5 on
TCP connection: 10.10.10.10:646 - 14.14.14.14:15188; MD5 on
TCP connection: 5.5.5.5:646 - 14.14.14.14:29837; MD5 on
```

12. **ICMP unreachable:** These packets can be disabled so router CPUs don't have to create tons of replies in response to a DDoS attack. Disabling unreachables can also hide network topology when using traceroute. An alternative is to leave them on with policers to implement backscatter traceback techniques. This advanced example is demonstrated later, but for now, we will disable ICMP unreachables on the external-facing links of XRv1 and CSR4. This is a very basic feature and is not discussed further after brief verification. Not surprisingly, the configuration is nearly identical for IPv6 as only the verbiage changes. XR is shown first.

```
RP/0/0/CPU0:XRv1#show ipv4 interface gig0/0/0/0.513 | include unreach
ICMP unreachables are always sent
RP/0/0/CPU0:XRv1#show ipv6 interface gig0/0/0/0.513 | include unreach
ICMP unreachables are enabled
```

```
! XRv1
interface GigabitEthernet0/0/0/0.513
ipv4 unreachables disable
interface GigabitEthernet0/0/0/0.513
ipv6 unreachables disable
```

```
RP/0/0/CPU0:XRv1#show ipv4 interface gig0/0/0/0.513 | include unreach
ICMP unreachables are never sent
RP/0/0/CPU0:XRv1#show ipv6 interface gig0/0/0/0.513 | include unreach
ICMP unreachables are disabled
```

The configuration on XE is just as easy and is shown below.

```
R4#show ip interface gig2.514 | include unreach
ICMP unreachables are always sent
R4#show ipv6 interface gig2.514 | include unreach
ICMP unreachables are sent
```

```
! CSR4
interface GigabitEthernet2.514
no ip unreachables
no ipv6 unreachables
```

```
R4#show ip interface gig2.514 | include unreach
  ICMP unreachables are never sent
R4#show ipv6 interface gig2.514 | include unreach
  ICMP unreachables are disabled
```

Both XE and XR have mechanisms to automatically rate-limit the local generation of ICMP unreachables for IPv4 only. First, we look at CSR4. I typically disable this feature in a lab environment but will re-enable it only on CSR4 for this demonstration. The default setting is to allow the router to issue ICMP unreachables once every 500 ms. There is additional granularity with respect to DF-bit (packet-too-big) unreachables since those are critical for PMTUD to function properly.

```
! CSR4 (command is enabled by default)
ip icmp rate-limit unreachable 500
```

```
R4#show ip icmp rate-limit
```

	DF bit unreachables	All other unreachables
Interval (millisecond)	500	500

Interface	# DF bit unreachables	# All other unreachables
-----	-----	-----
GigabitEthernet2.514	0	0
GigabitEthernet2.546	0	0
Loopback0	0	0

We will adjust the default policer on CSR4. I will allow DF unreachables to be sent at 100 ms intervals (more liberal) and will also log excessive unreachable generation if more than 10 unreachables are supposed to be generated in a single interval. Logs will be placed 60 seconds apart. This may be appropriate in a network where PMTUD is commonly used by hosts; it also enables extra security by logging excessive unreachables. All other unreachables still follow the 500 ms interval.

```
! CSR4
ip icmp rate-limit unreachable DF 100 log 10 60000
```

```
R4#show ip icmp rate-limit
```

	DF bit unreachables	All other unreachables
Interval (millisecond)	100	500
Log threshold (packet)	10	10
Log interval (millisecond)	60000	60000

Interface	# DF bit unreachables	# All other unreachables
-----	-----	-----
GigabitEthernet2.514	0	0
GigabitEthernet2.546	0	0
Loopback0	0	0

In XR, the configuration is similar. We will examine XRv1. I have not found a show command for the feature but it does appear to work. Logging is also not supported. In this example, I set the DF interval to 100 ms like before, and also reduce the other-unreachables limit down to 300 ms.

```
! XRv1
icmp ipv4 rate-limit unreachable DF 100
icmp ipv4 rate-limit unreachable 300
```

13. **Input hold-queue:** This represents the input FIFO queue per interface. The default depth is 75 packets, but Cisco recommends using 1500. This modification requires more memory, but if the value is too low, it could negatively influence selective packet discard (SPD), discussed later. We configure all XE routers to meet this specification, then verify it. Since the XR hardware platforms often handle this sort of thing at the line-card level (in a traffic manager process), we would apply MQC to the interface and adjust the queue depth in class default. The QoS section showed us that XRv won't accept this configuration, so we will skip XR to focus on CSR4 and CSR8. I only show the configuration from CSR8 since it is identical on CSR4. Notice that the command is per physical interface; my current design uses a single physical interface for testing, but in real life, dedicated physical interfaces should be used to face internally and externally.

```
! CSR8
interface GigabitEthernet2
  hold-queue 1500 in
```

```
R8#show interfaces gig2 | include Input
Input queue: 0/1500/0/0 (size/max/drops/flushes); Total output drops: 0
```

14. **Selective packet discard (SPD):** SPD is used to create a global pool of buffers to add "headroom" to the input queues for important packets (IGP, BGP, keepalives etc). Cisco advises increasing this headroom from 100 to 1000 packets, memory permitting (this is the new default on XE). This feature is not supported for XR or IPv6, and is a hidden command on XE. We only evaluate it because it is explicitly listed in Cisco's best-practices document. After the input queue is full, SPD offers a mechanism for important, router-destined traffic to not be dropped. The admission criteria for this headroom include things like BGP, IGP, and IPP6 traffic. Even beyond this headroom is the "extended headroom" which is even more stringent on entry criteria and is used when the headroom is full. This includes layer 2 keepalives, LDP (in some versions), and ARP, as examples. Packets of a low priority, such as an IPP0 ping, can never enter the headroom or extended headroom. A BGP packet could never enter the extended headroom, but is allowed in the regular headroom. The SPD "mode" is deprecated and used to mean the difference between accepting any packet (normal) versus rejected all malformed packets (aggressive). Routers nowadays always reject malformed packets and the "ip spd mode aggressive" command does nothing. We can see the default settings with "show ip spd".

```
R8#show ip spd
Current mode: normal.
```

```
Queue min/max thresholds: 73/74, Headroom: 1000, Extended Headroom: 10
IP normal queue: 0, priority queue: 0.
SPD special drop mode: none
```

Notice the queue thresholds. These are based on the default input-queue value of 75. When the packets in the queue are between min and max, random dropping occurs. In this case, that virtually never happens, because the two are adjacent numbers. In our case, we need to tune these values so they better reflect our new input queue size. When the input queue is full and the traffic is not a candidate for SPD headroom, all packets are tail dropped.

```
! CSR8
ip spd queue max 1499
ip spd queue min 1000
```

We will also increase the headroom and extended headroom as Cisco recommends. We will set both standard headroom and extended headroom values to 1500 for good measure. Notice these commands are not prefixed with “ip” unlike the previous commands, for some reason.

```
! CSR8
spd headroom 1500
spd extended 1500
```

We can see the final result of our configuration to ensure all our new changes were successful. All of these commands are hidden in the parser, as previously mentioned.

```
R8#show ip spd
Current mode: normal.
Queue min/max thresholds: 1000/1499, Headroom: 1500, Extended Headroom: 1500
IP normal queue: 0, priority queue: 0.
SPD special drop mode: none
```

15. Control-plane policing and Local Packet Transport Service (CPP and LPTS): On XE and XR respectively, these features police packets destined to the router itself. It is often used to prevent against DDoS attacks targeting network devices that try to hog resources. This can cause critical router processes, such as BGP/IGP, to fail. These features are examined in detail in a dedicated section.

49.2 Management plane security best practices

1. Disable unnecessary services: Disabling features not needed will reduce the number of attack vectors. In our environment, I’ve selected a handful of uncommonly used services to demonstrate the process. Many of these are off by default, but this may change between versions. Note that disabling “service dhcp” disables server, client, and relay functionality.

```
! IOS and XE “unnecessary” services
no service tcp-small-servers
```

```
no service udp-small-servers
no service dhcp
no service pad
no service config
no service finger
no service call-home
```

All four of the following services are off by default in XR.

```
! XR "unnecessary" services
no service ipv4 tcp-small-servers
no service ipv4 udp-small-servers
no service ipv6 tcp-small-servers
no service ipv6 udp-small-servers
```

2. **Appropriate banners:** Banners often serve to detail the legal consequences of attacking the system. I just made a quick message-of-the-day (motd) banner to demonstrate this, but normally there would be login, exec, and incoming banners also. The configuration is identical in XE and XR.

```
! All BGP AS 85 XE and XR routers
banner motd %
*** Warning: Protected system ***
%
```

3. **Enable secret:** The word “secret” in this context refers to a password used to protect privileged access to the router. It does not apply to XR since there is always a username/password.

```
! CSR6
enable secret TEST_PASS
```

4. **Exec-timeout on CON/VTY lines:** This feature prevent an exec shell from staying open forever. I’ve set these to never timeout for lab use, but they are tunable. More realistic settings could use a 10 minute VTY timeout with a 30 minute console timeout. The first digit is minutes and the last is seconds.

```
! CSR8
line con 0
exec-timeout 0 0
```

```
! XRv1
line console
exec-timeout 0 0
```

5. **TCP-keepalives:** This feature enforces a timeout inactive or dysfunctional TCP sessions by issuing keepalives. Automatically enabled in XR and not configurable. Not enabled in XE by default. Enabling them bidirectionally on both routers makes the most sense, so either side can tear down the session if connectivity is lost.

```
! CSR6 and CSR8
service tcp-keepalives-in
service tcp-keepalives-out
```

As a quick test, we will telnet from CSR6 to CSR8, then check the session details. We can see that CSR8 shows the keepalive feature enabled for this telnet session. If there is a network outage and no activity is seen from the TCP client, the session is torn down after about 5 minutes.

```
R6# telnet 85.6.8.8
Trying 85.6.8.8 ... Open
```

```
*** Warning: Protected system ***
```

```
R8#show tcp brief | include 85\.6
7F0DD04C0178 85.6.8.8.23 85.6.8.6.38383 ESTAB
```

```
R8#show tcp tcb 7F0DD04C0178 | include ^Option
Option Flags: keepalive running, Retrans timeout
```

6. VTY access-class (ACL) security: This can prevent certain networks/hosts from accessing the device. I've added a very liberal ACL to demonstrate this on CSR8 and XRv1. It doesn't allow loopbacks in my network to telnet in, but allows sessions to or from any transit link.

```
! CSR8
ip access-list standard ACL_VTY_ACCESS
 permit 85.0.0.0 0.255.255.255

line vty 0 4
 access-class ACL_VTY_ACCESS in
 access-class ACL_VTY_ACCESS out
```

XR VTY line configuration is rather complex. First, we need to say how many telnet server instances (concurrent connections) we allow. We then create a line template that we can apply to lines later on. Under this template, we apply our security controls; we use the same ACL logic shown above for CSR8. Last, we create a VTY pool to identify which VTY lines can be used (0 through 4) and specify the template that defines the line parameters.

```
! XRv1
ipv4 access-list ACL_VTY_ACCESS
 10 permit ipv4 85.0.0.0 0.255.255.255 any

telnet vrf default ipv4 server max-servers 3

line template VTY
 access-class ingress ACL_VTY_ACCESS
```

```
access-class egress ACL_VTY_ACCESS

vty-pool default 0 4 line-template VTY
```

7. **Usage of SSHv2:** SSHv2 is more secure than SSHv1 and telnet for device management. We will extend the security of the previous configuration to disable telnet and enable SSHv2 on XRv1 and CSR8. SSH requires a username/pass login. This is unlike telnet which, in the most lenient case, requires no authentication. We must define a domain-name before we can generate our RSA keys used for SSH. We also will disable telnet as an option in our incoming VTY line stanza, which ensures telnet is never allowed for managing CSR8. Then, we configure some extra SSH options, including logging and version 2.

```
! CSR8
username ssh privilege 15 password ssh
ip domain-name lab.local
crypto key generate rsa modulus 1024

line vty 0 4
  transport input none
  transport input ssh
  login local

ip ssh ver 2
ip ssh authentication-retries 2
ip ssh logging events
```

A successful SSH session from an SSH client (CSR6) creates a detailed log message. After logging in, CSR6 logs out, which is also a logged event.

```
! CSR8, when CSR6 logs in
%SSH-5-SSH2_SESSION: SSH2 Session request from 85.6.8.6 (tty = 0) using
crypto cipher 'aes128-ctr', hmac 'hmac-sha1' Succeeded
%SSH-5-SSH2_USERAUTH: User 'ssh' authentication for SSH2 Session from
85.6.8.6 (tty = 0) using crypto cipher 'aes128-ctr', hmac 'hmac-sha1'
Succeeded

! CSR8, when CSR6 logs out
%SSH-5-SSH2_CLOSE: SSH2 Session from 85.6.8.6 (tty = 0) for user 'ssh' using
crypto cipher 'aes128-ctr', hmac 'hmac-sha1' closed
```

A failed session also creates a log message. Don't be fooled by the first message that says the session opened; this is the low-level TCP negotiation process. The user failed to enter the proper password which means authentication ultimately failed.

```
! CSR8, when CSR6 uses the incorrect password
```

```
%SSH-5-SSH2_SESSION: SSH2 Session request from 85.6.8.6 (tty = 0) using
crypto cipher 'aes128-ctr', hmac 'hmac-sha1' Succeeded
R8(config)#
%SSH-5-SSH2_USERAUTH: User 'ssh' authentication for SSH2 Session from
85.6.8.6 (tty = 0) using crypto cipher 'aes128-ctr', hmac 'hmac-sha1' Failed
%SSH-5-SSH2_CLOSE: SSH2 Session from 85.6.8.6 (tty = 0) for user 'sh' using
crypto cipher 'aes128-ctr', hmac 'hmac-sha1' closed
```

In XR, having already defined the VTY pool, we only need to enable SSH and our RSA keys. Note that the RSA keys are generated in exec mode, unlike XE. XR also does not appear to require an explicitly-defined domain-name before trying to generate RSA keys for SSH.

```
! XRv1
ssh server v2
ssh server logging
ssh server session-limit 3

! XRv1 exec mode
crypto key generate rsa general-keys
```

Below is a successful and failed login, with messages similar to those seen in XE.

```
! XRv1, successful login from CSR5
RP/0/0/CPU0:20:43:46.455 : SSHD_[65713]: %SECURITY-SSHD-6-INFO_SUCCESS :
Successfully authenticated user 'nrusso' from '85.1.5.5' on 'vty0' (cipher
'aes128-cbc', mac 'hmac-sha1')

! XRv1, failed login from CSR5
RP/0/0/CPU0:20:43:58.474 : SSHD_[65713]: %SECURITY-SSHD-4-INFO_FAILURE :
Failed authentication attempt by user 'nrusso' from '85.1.5.5' on 'vty0'
RP/0/0/CPU0:20:43:59.664 : SSHD_[65713]: %SECURITY-SSHD-3-ERR_GENERAL :
Failed to receive User authentication request
```

8. **One-time passwords:** Useful for when SSH is not available on a device or when you know a user will only need to access a device one time. We will demonstrate this on CSR6. There are two caveats with this feature that may not be obvious. First, if a user logs in using some other username, the one-time password is not deleted. Second, once the one-time user logs in, the username is removed from the running-config, so if the startup-config still has it, a reboot will restore the one-time user/password.

```
! CSR6
username ONCE one-time password ONCE

R6#show run | include ONCE
username ONCE one-time password 0 ONCE
```

We log into CSR6 once from CSR5 successfully.

```
R5#telnet 6.6.6.6
Trying 6.6.6.6 ... Open
```

```
Username: ONCE
Password: ONCE
```

```
R6>
```

After exiting, we cannot log in again. CSR6 has removed the “ONCE” username from its running configuration. Reloading CSR6 would technically work to generate another one-time login, assuming the command was written to the startup configuration.

```
R5#telnet 6.6.6.6
Trying 6.6.6.6 ... Open
```

```
Username: ONCE
Password: ONCE
```

```
% Login invalid
```

```
R6#show run | include ONCE
[no output]
```

9. **AAA:** Authentication, Authorization, and Accounting (AAA) is a subsystem that centralizes these 3 features in a RADIUS or TACACS server. RADIUS and TACACS can be sizable topics if one looks at all the options. The general idea is to centralize certain network security functions so individual logins need not exist on every device. It can also be used for 802.1x, which is a port-based authentication mechanism on switches capable of assigning VLANs based on authentication level.

AAA server configuration on IOS-like platforms (XE) has changed in recent releases to be more modular, much like XR. On CSR3, I configure a pair of RADIUS servers, one using the new ports (authentication port 1812, accounting port 1813) and one using the old ports (auth 1645, acct 1646). Both point to a notional RADIUS server; one is IPv4 and one is IPv6. I’ve added some extra variation; the retransmit option is simply a retry count for accessing the server, and the timeout is measured in seconds for a response to be considered inconclusive. The automated tester works like IP SLA where it just tests reachability to the RADIUS server. Normally this can be done with the “test” exec-level command, but an automated mechanism is useful also.

```
! CSR3
radius server RADIUS_NEW_IPV6
  address ipv6 ::1:2:3:4 auth-port 1812 acct-port 1813
  timeout 1
  retransmit 3
  key RAD_KEY

radius server RADIUS_OLD_IPV4
```

```
address ipv4 1.2.3.4 auth-port 1645 acct-port 1646
automate-tester username RAD_TEST probe-on ignore-acct-port
key RAD_KEY
```

Below, we examine the server statistics. Because the first server isn't actively doing anything, I removed the long list statistics full of zeroes. The second server is trying to authenticate the user RAD_TEST and failing due to timeout. We see a different statistic stanza for authentication, authorization, and accounting. Interestingly, the router thinks the first server is up, probably because nothing has failed yet. The second server is considered "dead" as a result of the automated test failures.

```
R3#show aaa servers
```

```
RADIUS: id 1, priority 1, host ::1:2:3:4, auth-port 1812, acct-port 1813
```

```

```

```
Estimated Outstanding Access Transactions: 0
```

```
Estimated Outstanding Accounting Transactions: 0
```

```
Estimated Throttled Access Transactions: 0
```

```
Estimated Throttled Accounting Transactions: 0
```

```
Maximum Throttled Transactions: access 0, accounting 0
```

```
Requests per minute past 24 hours:
```

```
high - 0 hours, 1 minutes ago: 4
```

```
low - 0 hours, 2 minutes ago: 0
```

```
average: 2
```

We can manually test a AAA server from exec mode as mentioned above. Even with the failed test of trying to reach the IPv6 server, the output still says up. We see exactly 4 failed requests, because there were 3 retries after the first failure, as we configured.

```
R3#test aaa group radius server name RADIUS_NEW_IPV6 RAD_USER rad_pass legacy
Attempting authentication test to server-group radius using radius
No authoritative response from any server.
```

```
R3#show aaa servers
RADIUS: id 1, priority 1, host ::1:2:3:4, auth-port 1812, acct-port 1813
  State: current UP, duration 438s, previous duration 0s
  Dead: total time 0s, count 0
  Quarantined: No
  Authen: request 4, timeouts 4, failover 0, retransmission 3
    Response: accept 0, reject 0, challenge 0
    Response: unexpected 0, server error 0, incorrect 0, time 0ms
    Transaction: success 0, failure 1
[snip]
```

We can also group servers together. For example, we might want to use both servers as potential candidates for login authentication. I also demonstrate adding a “private” RADIUS server which can only be accessed by referencing the group. So, the group contains three servers, two public and one private. The show command referencing the group reveals all servers encompassed by the group, seen below.

```
! CSR3
aaa group server radius RAD_GROUP
  server name RADIUS_NEW_IPV6
  server name RADIUS_OLD_IPV4
  server-private 4.3.2.1 key RAD_KEY

R3#show radius server-group RAD_GROUP
Server group RAD_GROUP
  Sharecount = 1  sg_unconfigured = FALSE
  Type = standard  Memlocks = 1
  Server(::1:2:3:4:1812,1813) Transactions:
    Authen: 0  Author: 0  Acct: 0
  Server_auto_test_enabled: FALSE
  Keywrap enabled: FALSE
  Server(1.2.3.4:1645,1646) Transactions:
    Authen: 0  Author: 0  Acct: 0
  Server_auto_test_enabled: TRUE
  Keywrap enabled: FALSE
  Server(4.3.2.1:1645,1646) Transactions:
    Authen: 0  Author: 0  Acct: 0
  Server_auto_test_enabled: FALSE
  Keywrap enabled: FALSE
```

This server group can be added a “method-list” for authentication. For PPP authentication, such as PAP, CHAP, and EAP, we use this server group by default. If it fails, then AAA will fall back to the local database. Be careful when enabling AAA globally; it automatically relies on local logins for VTY lines unless manually overridden.

```
! CSR3
aaa new-model
aaa authentication ppp default group RAD_GROUP local

R3#show aaa method-lists authentication | include PPP|RAD_GROUP
  authen queue=AAA_ML_AUTHEN_PPP
    name=default valid=TRUE id=0 :state=ALIVE : SERVER_GROUP RAD_GROUP LOCAL
```

TACACS+ configuration is almost identical, with only small changes. Here is a mirrored configuration from the RADIUS example, with two public TACACS servers and one private TACACS server in a server group. I also show the verification quickly; despite being a AAA server, it doesn’t show under the show commands for AAA in all categories. The TCP port for TACACS is 49; I change this to 94 for the IPv6 server for variety. Notice that the output annotates which servers are “public” and which are “private”; the AAA show commands used above for RADIUS servers did not reveal this.

```
! CSR3
aaa group server tacacs+ TAC_GROUP
  server name TAC_OLD_IPV4
  server name TAC_NEW_IPV6
  server-private ::4:3:2:1 key TAC_KEY

tacacs server TAC_NEW_IPV6
  address ipv6 ::1:2:3:4
  key TAC_KEY
  port 94
  single-connection

tacacs server TAC_OLD_IPV4
  address ipv4 1.2.3.4
  key TAC_KEY

R3#show tacacs
Tacacs+ Server - public :
    Server name: TAC_NEW_IPV6
    Server address: ::1:2:3:4
    Server port: 94
    Socket opens: 0
    Socket closes: 0
    Socket aborts: 0
    Socket errors: 0
    Socket Timeouts: 0
    Failed Connect Attempts: 0
```

```
Total Packets Sent:      0
Total Packets Recv:      0
Expected Replies:        0
```

```
Tacacs+ Server - public :
    Server name: TAC_OLD_IPV4
    Server address: 1.2.3.4
    Server port: 49
[snip]
```

```
Tacacs+ Server - private :
    Server address: ::4:3:2:1
    Server port: 49
[snip]
```

Let's assume this group should also be used for PPP authentication but for a custom link. We define a non-default method-list and bind the TACACS server group to it. Under the PPP interface, we would reference this method-list for authentication (not configured) as needed.

```
! CSR3
aaa authentication ppp CUSTOM group TAC_GROUP none

R3#show aaa method-lists authentication | include PPP|CUSTOM
authen queue=AAA_ML_AUTHEN_PPP
    name=CUSTOM valid=TRUE id=D1000003 :state=ALIVE : SERVER_GROUP TAC_GROUP
NONE
```

XR's configuration is very similar to XE, except there does not appear to be IPv6 host support in v5.3.0. Rather than define a server name, we just specify the host address and ports in the initial server definition. I define two public servers and one private server, wrapped in a server group. One of the public servers has automated testing enabled, so I created a fake user for that. Within the group there are various load sharing options so all servers can be used "equally". I also specify the RADIUS source interface, which is a common practice to ensure consistent reachability, especially in an SP core with IGP prefix-suppression enabled.

```
! XRv2
radius source-interface Loopback0 vrf default
radius-server host 1.2.3.4 auth-port 1645 acct-port 1646
    key 7 1425332F332F0F12
    timeout 1
    test username RAD_TEST
    retransmit 3
    ignore-acct-port

radius-server host 4.3.2.1 auth-port 1812 acct-port 1813
    key 7 1425332F332F0F12
```

```

username RAD_TEST
  group operator
  password 7 122B24332D20293D

aaa group server radius RAD_GROUP
  server 4.3.2.1 auth-port 1812 acct-port 1813
  server 1.2.3.4 auth-port 1645 acct-port 1646
  load-balance method least-outstanding batch-size 25
  server-private 6.7.8.9 auth-port 1645 acct-port 1646
  key 7 0121272064202336

```

A few basic show commands can verify our configuration. The outputs are not discussed in detail because they are very similar to XE outputs. Notice that the first server has automated testing enabled, which is failing because the RADIUS server is imaginary. The last server is private and is only accessible by invoking the server-group RAD_GROUP. Like the XE show commands for TACACS, this output shows us which servers are “public” and which are “private”.

```

RP/0/0/CPU0:XRv2#show radius authentication
Server: 1.2.3.4, port: 1645/
  0 requests, 0 pending, 0 retransmits
  0 accepts, 0 rejects, 0 challenges
  0 timeouts, 0 bad responses, 0 bad authenticators
  0 unknown types, 0 dropped, 0 ms latest rtt
  Throttled: 0 transactions, 0 timeout, 0 failures
  Estimated Throttled Access Transactions: 0
  Maximum Throttled Access Transactions: 0
  Automated TEST Stats:
    1141 requests, 1141 timeouts, 0 response, 0 pending

Server: 4.3.2.1, port: 1812/
  [snip]

Server: 6.7.8.9, port: 1645/ [RAD_GROUP / private]
  [snip]

```

```

RP/0/0/CPU0:XRv2#show radius source-interfaces
Interface          IP-Address          VRF Id
Loopback0          12.12.12.12         0x60000000

```

```

RP/0/0/CPU0:XRv2#show radius server-groups
Global list of servers
  Contains 2 server(s)

```

```

Server 1.2.3.4/1645/1646  is DEAD

```

```

Server 4.3.2.1/1812/1813  is UP

```

```

Server group 'RAD_GROUP' has 3 server(s)

```

```
Dead time: 0 minute(s) (inherited from global)
Contains 3 server(s)
```

```
Server 4.3.2.1/1812/1813 is UP
```

```
Server 1.2.3.4/1645/1646 is DEAD
```

```
Server 6.7.8.9/1645/1646 [private] is UP
```

The RADIUS group is bound identically to XE, where it can be applied to a method-list for any type of authentication/authorization that supports RADIUS server groups. We use the PPP example again.

```
! XRv2
aaa authentication ppp RAD_PPP group RAD_GROUP local
```

TACACS+ configuration in XR is almost identical except introduces some TACACS-specific features and terms. We set the TACACS DSCP to CS6 globally for IPv6 packet; this will increase the probability of TACACS traffic reaching the server when originated. The configuration is shown below.

```
! XRv2
tacacs-server host ::1:2:3:4 port 49
  key 7 06322E0273652C20
  single-connection

tacacs-server host ::5:4:2:1 port 94
  key 7 1331363134272113

aaa group server tacacs+ TAC_GROUP
  server ::5:4:2:1
  server ::1:2:3:4
  server-private 1.2.3.4 port 49
  key 7 073B006F71223C3C

tacacs-server ipv6 dscp cs6
```

The verification is almost similar to RADIUS. We can see the private server marked as such, but otherwise there is no TACACS activity at present.

```
RP/0/0/CPU0:XRv2#show tacacs
Server: ::1:2:3:4/49 opens=0 closes=0 aborts=0 errors=0
  packets in=0 packets out=0
  status=up single-connect=true family=IPv6

Server: ::5:4:2:1/94 opens=0 closes=0 aborts=0 errors=0
  packets in=0 packets out=0
  status=up single-connect=false family=IPv6
```

```
Server: 1.2.3.4/49 vrf=default [private]
      opens=0 closes=0 aborts=0 errors=0
      packets in=0 packets out=0
      status=up single-connect=false family=IPv4
```

10. **Local passwords:** Local passwords are irreversibly encrypted and used as last resort to manage a device. Newer versions of IOS support SHA256 and SCRYPT mechanisms, in addition to MD5, for securing the password. PBKDF2 and SCRYPT are both key derivation functions (KDFs), and are more secure than MD5. The technical differences between the two are beyond the scope of CCIE SP, but Cisco seems to hint that SCRYPT is more secure.

```
R6(config)#username SECRET_USER algorithm-type ?
  md5      Encode the password using the MD5 algorithm
  scrypt   Encode the password using the SCRYPT hashing algorithm
  sha256   Encode the password using the PBKDF2 hashing algorithm
```

```
! CSR6
username SECRET_USER algorithm-type scrypt secret password
```

The enter result is an enormous hashed password string, which is very hard to crack. MD5 was considered level 5. In terms of new features, PBKDF2 is level 8 and SCRYPT is level 9. Looking at the configuration, we can see the level 9 password encryption.

```
R6#show running-config | include SECRET_USER
username SECRET_USER secret 9
$9$8dXXbV3TNlYym8$fsIu5emmXjFRyJjba.ps8QUSKy5Iz3HlhDzm3ai82Vw
```

XR only appears to support the MD5 method, as no options are available for anything newer.

```
! XRv1
username SECRET_USER
  secret 5 $1$JeSw$qf3PnPhDVZiElr/Icj3H5/
```

11. **Privilege level tuning:** This technique is based on the premise of only granting users “just enough” privilege to do their jobs. On CSR7, we create a JUNIOR_PRIV account for a junior engineer. At privilege level 5, we grant access to all show and debug commands, but no configuration or test commands, for example.

```
! CSR7
username JUNIOR_PRIV privilege 5 nopassword
privilege exec all level 5 show
privilege exec all level 5 debug
privilege exec all level 5 undebug
```

We log into CSR7 using this new username and quickly verify that our user changes to reflect this new user. Any activities done by this user will be logged as such (if logging is configured).

```
R7#login
```

```
Username: JUNIOR_PRIV
```

```
R7#show users
```

Line	User	Host(s)	Idle	Location
* 0 con 0	JUNIOR_PRI	idle	00:00:00	

The user has access only to the commands at level 5 and below, which include only show, debug, and undebug commands. This is effectively a “read-only” view of the router.

```
R7#debug ?
```

aaa	AAA Authentication, Authorization and Accounting
access-expression	Boolean access expression
[snip]	

```
R7#show ?
```

aaa	Show AAA values
access-expression	List access expression
[snip]	

```
R7#undebug ?
```

aaa	AAA Authentication, Authorization and Accounting
access-expression	Boolean access expression
[snip]	

```
R7#test ?
```

```
% Unrecognized command
```

```
R7#configure ?
```

```
% Unrecognized command
```

XR does not appear to support this legacy feature and instead implements a flavor of RBAC.

12. **RBAC:** Role-Based Access Control is a more modular way of adjusting user privileges. In this way, we create “views” which define what a user can do. Users are then assigned views which determine their privileges upon the creation of an exec shell. This is more flexible and intuitive than the privilege method. On CSR7, I create a few roles with various requirements:

- SHOW_ISIS: can only execute “show” commands relating to IS-IS
- DEBUG_ISIS: can only execute “debug” commands relating to IS-IS
- ALL_ISIS: able to execute any “show” or “debug” commands relating to IS-IS

We will define three separate roles (known as “views”) to describe the capabilities of each category, then optionally assign them to usernames. There is also a hidden “root” view that gives full access.

```
! CSR7
parser view SHOW_ISIS
  secret 5 $1$A/Az$3x8cHb/Gq.asVZZRjuPa00
  commands exec include all show isis
  commands exec include all show ip
  commands exec include show

parser view DEBUG_ISIS
  secret 5 $1$F/vA$qFQWdvXO/tSvluHjkQWl41
  commands exec include all undebug isis
  commands exec include all undebug
  commands exec include all debug isis
  commands exec include debug

parser view ALL_ISIS superview
  secret 5 $1$r1m8$9CLQrKv2IjLW9pKZzQPgm.
  view SHOW_ISIS
  view DEBUG_ISIS
```

From the shell, you can either log in as a user with a view or manually select the view using the “enable” command. Below we see an error that AAA must be configured. Once that is done, we can see the view works properly.

```
R7#enable view ALL_ISIS
% AAA must be configured.
```

```
! CSR7
aaa new-model
aaa authentication login default local
```

After enabling a basic AAA for local login, we can change the view. We verify that we have all the show and debug commands for IS-IS with this view. The commands don’t include other features, as expected, since those were not included in the view.

```
R7#enable view ALL_ISIS
Password: [the view password goes here]
```

```
R7#show parser view
Current view is 'ALL_ISIS'
```

```
R7#show ?
  banner      Display banner information
  bootflash:  display information about bootflash: file system
  flash:      display information about flash: file system
```

ip	IP information
isis	IS-IS routing information
parser	Display parser information

R7#show isis ?

*	All IS-IS address families
WORD	IS-IS Process tag (use "null" for no tag)
database	IS-IS link state database

R7#debug ?

isis	IS-IS Information

R7#debug isis ?

*	All IS-IS address families
WORD	IS-IS Process tag (use "null" for no tag)
adj-packets	IS-IS Adjacency related packets

On XR, there are several pre-made groups. The groups are pretty self-explanatory and the documentation spells out the specifics of each. The XR constructs require administrators to determine a set of tasks (taskgroup) and then assign those sets of tasks to sets of users (usergroup). Users themselves inherit from usergroups, creating a 3-level hierarchy. I have defined a few custom task groups to manage IGP/LDP and MPLS functionality, and then referenced them from an MPLS management user group. MPLS administrators would be placed into this user group, ideally. The task options are read, write, execute, and debug.

```
! XRv4
taskgroup MPLS
  task read l2vpn
  task read mpls-te
  task write l2vpn
  task write mpls-te
  task execute l2vpn
  task execute mpls-te
  task debug mpls-te

taskgroup IGP_LDP
  task read isis
  task read mpls-ldp
  task execute isis
  task execute mpls-ldp
  task debug isis
  task debug mpls-ldp

usergroup MPLS_MGR
  taskgroup MPLS
  taskgroup IGP_LDP
  description MANY MPLS RELATED TASKS
```

```
username MPLS_GUY
group MPLS_MGR
password 7 15020A1F173D24362C
```

If we log in as MPLS_GUY, we have no mechanism to change/modify IS-IS or LDP since the “write” permission was not granted in the union of all permissions between all inherited task-groups. We also cannot debug L2VPN, but we can configure it. We can verify permissions and our own identity with some basic commands. Once we verify this, we test out our capabilities to ensure the restricted permissions are in effect. Rather than suggest the command is “unrecognized” as XE does, XR is more honest by saying a user is not authorized to perform a specific action.

```
RP/0/0/CPU0:XRv4#show user
```

```
MPLS_GUY
```

```
RP/0/0/CPU0:XRv4#show user tasks
```

```
Task:          isis      : READ          EXECUTE      DEBUG
Task:          l2vpn     : READ          WRITE        EXECUTE
Task:          mpls-ldp   : READ          EXECUTE      DEBUG
Task:          mpls-te    : READ          WRITE        DEBUG
```

```
RP/0/0/CPU0:XRv4(config)#mpls ldp
```

```
% This command is not authorized
```

```
RP/0/0/CPU0:XRv4(config)#router isis 1
```

```
% This command is not authorized
```

```
RP/0/0/CPU0:XRv4#debug l2vpn ?
```

```
% This command is not authorized
```

This user is authorized to look at IS-IS/LDP information, as well as configure global MPLS-TE parameters.

```
RP/0/0/CPU0:XRv4#show mpls ldp neighbor brief
```

Peer	GR	NSR	Up Time	Discovery		Addresses		Labels	
				ipv4	ipv6	ipv4	ipv6	ipv4	ipv6
2.2.2.2:0	N	N	21:13:22	2	0	5	0	11	0
3.3.3.3:0	N	N	21:13:16	1	0	3	0	13	0
10.10.10.10:0	N	N	21:13:12	1	0	13	0	8	0
5.5.5.5:0	N	N	21:13:12	1	0	6	0	16	0

```
P/0/0/CPU0:XRv4#show isis neighbors summary
```

```
IS-IS 1 neighbor summary:
```

State	L1	L2	L1L2
Up	3	2	0

```
RP/0/0/CPU0:XRv4(config)#mpls traffic-eng ?
```

```
affinity-map          Affinity Map Configuration
[snip]
```

The “execute” option relates to things from the exec shell, such as direct operations on a feature or using the “clear” command. We do not have execute permissions for MPLS-TE, so we cannot reoptimize tunnels for example. We could clear IS-IS neighbors or MPLS LDP neighbors, though.

```
RP/0/0/CPU0:XRv4#clear isis ?
  afi-all      IPv4 and IPv6 commands
  instance      Clear data from a single IS-IS instance
[snip]
```

```

  oam   OAM information
```

```
RP/0/0/CPU0:XRv4#mpls ?
      ^
```

```
% Invalid input detected at '^' marker.
```

13. **Auditing/tracking configurations:** This ensures that there are no unauthorized changes to device configurations over time. This is more of a policy application than configuration. XR handles this automatically with the commit list and rollback feature. XE can use the “archive” feature to accomplish a similar mechanism of backing up configurations, demonstrated on CSR2. I create a folder on the bootflash for the configurations (“configs”), then tell the archive feature to store up to 5 copies of backups. **You must include the filename prefix in the path, not just a folder, or else archive does nothing.** This occurs automatically every time I save the configuration, also. This works with “write memory” and the newer “copy run start”. You can also manually backup a configuration with “archive config”. I demonstrate all three methods below.

```
! CSR2
mkdir bootflash:/configs

archive
  path bootflash:/configs/ARCHIVE_CFG_
  maximum 5
  write-memory
```

We show that the folder was created successfully, then save the configuration on CSR2. This automatically archives the configuration to our “configs” directory as shown below.

```
R2#dir bootflash: | include configs
600289  drwx          4096  Jul 19 2015 21:01:14 +00:00  configs
```

```
R2#write memory
Building configuration...
```

[OK]

```
R2#dir bootflash:/configs
Directory of bootflash:/configs/
```

```
600290  -rw-      8300   Jul 19 2015 21:06:22 +00:00  ARCHIVE_CFG_-Jul-19-21-06-22.321-0
```

Below, I demonstrate the manual method. This creates another archive in the “configs” folder.

```
R2#archive config
```

```
R2#dir bootflash:/configs
Directory of bootflash:/configs/
```

```
600290  -rw-      8300   Jul 19 2015 21:06:22 +00:00  ARCHIVE_CFG_-Jul-19-21-06-22.321-0
600291  -rw-      9594   Jul 19 2015 21:06:39 +00:00  ARCHIVE_CFG_-Jul-19-21-06-39.060-1
```

Rather than use the “write memory” legacy command, the newer “copy run start” also works.

```
R2#copy running-config startup-config
```

```
Destination filename [startup-config]?
Building configuration...
[OK]
```

```
R2#dir bootflash:/configs
Directory of bootflash:/configs/
```

```
600290  -rw-      8300   Jul 19 2015 21:06:22 +00:00  ARCHIVE_CFG_-Jul-19-21-06-22.321-0
600291  -rw-      9594   Jul 19 2015 21:06:39 +00:00  ARCHIVE_CFG_-Jul-19-21-06-39.060-1
600292  -rw-      8300   Jul 19 2015 21:06:54 +00:00  ARCHIVE_CFG_-Jul-19-21-06-54.350-2
```

There is no configuration required in XR, but as a quick example, we can see the past configuration commits easily. I added a loopback999 interface in my last commit and added a brief “label” to it. I also added a longer comment which is revealed using the detail keyword. Other commits just have numeric, sequential labels (the label is set to the commit ID), and no comments. These labels/comments can be used for easy file identification when performing rollbacks.

```
RP/0/0/CPU0:XRv1(config)#commit label ADDED_LO99 comment this is cool
```

```
RP/0/0/CPU0:XRv1#show configuration commit list
```

SNo.	Label/ID	User	Line	Client	Time Stamp
1	ADDED_LO99	nrusso	con0_0_CPU0	CLI	[snip]
2	1000000156	nrusso	con0_0_CPU0	CLI	[snip]

```
RP/0/0/CPU0:XRv1#show configuration commit list detail
```

1) CommitId: 1000000157	Label: ADDED_LO999
UserId: nrusso	Line: con0_0_CPU0
Client: CLI	Time: [snip]

Comment: this is cool

2) CommitId: 1000000156	Label: NONE
UserId: nrusso	Line: con0_0_CPU0
Client: CLI	Time: [snip]

14. **Logging:** Logs should be sent to a few syslog servers for offline storage. Syslog commonly uses UDP 514 or sometimes TCP 601 for transport. I've configured two "syslog servers" using CSR5 as a syslog client to demonstrate the basic configuration. I instruct the router to send messages of severity level 5 or lower (lower numerically but higher priority) to the syslog servers, along with using its hostname as the ID inside the packet. Counters are shown below, and notice that the TCP-based logging is not working, as the session does not exist. UDP based transport is totally asynchronous and the messages are sent whether the target is a syslog server or not.

```
! CSR5
logging trap notifications
logging origin-id hostname
logging host ipv6 ::14:14:14:14 transport tcp
logging host 14.14.14.14
```

```
R5#show logging | section Trap
Trap logging: level notifications, 247 message lines logged
  Logging to ::14:14:14:14 (tcp port 601, audit disabled,
    link down),
    0 message lines logged,
    0 message lines rate-limited,
    0 message lines dropped-by-MD,
    xml disabled, sequence number disabled
    filtering disabled
  Logging to 14.14.14.14 (udp port 514, audit disabled,
    link up),
    6 message lines logged,
    0 message lines rate-limited,
    0 message lines dropped-by-MD,
    xml disabled, sequence number disabled
    filtering disabled
Logging Source-Interface:      VRF Name:
```

The XR configuration is similar, except I specify two different severity levels for the syslog hosts. I did not enable TCP transport, but notice that because no critical messages have occurred, the IPv6 server has not received any packets. I can also set the source interface and originator string inside the log message.

```
! XRv1
logging 14.14.14.14 vrf default severity info
logging ::14:14:14:14 vrf default severity critical
logging source-interface Loopback0
logging hostnameprefix XRv1
```

```
RP/0/0/CPU0:XRv1#show logging
Syslog logging: enabled (0 messages dropped, 0 flushes, 0 overruns)
  Console logging: level debugging, 525 messages logged
  Monitor logging: level debugging, 274 messages logged
  Trap logging: level notice, 2 messages logged
  Logging to 14.14.14.14, 2 message lines logged
  Logging to ::14:14:14:14, 0 message lines logged
  Buffer logging: level debugging, 799 messages logged
[snip]
```

Different severity levels of logs can be sent to different output devices. Below are output devices:

- a. **Console:** writes to the console, which is self explanatory. VTY users will not see it.
- b. **Monitor:** writes to TTY sessions, not enabled by default, users use “terminal monitor” to enable.
- c. **Trap:** writes to the configured syslog servers (not related to SNMP traps).
- d. **Buffered:** writes to the local log, in memory, which is non persistent. File logging is available on Catalyst platforms and possibly a few others. The buffer is circular and it has limited size.
- e. **History:** When syslog messages are generated, “history” will wrap them in SNMP traps and send to SNMP servers. There is a history table size that determines how many logs can be stored. This was the original syslog/SNMP-trap interworking operation which has since changed.
- f. **SNMP-trap:** A new command that details when traps are sent. The history table stores the most recent entries and if this command is set, determines when to send SNMP traps to the syslog servers.

The history and SNMP-trap options require some additional explanation. Enabling logging history created a history table of length 1, which holds only the most recent syslog entry. Every syslog has an entry number, the most recent being 95. When the table is full, this number minus the maximum table size will equal the number of entries flushed ($95 - 1 = 94$). Essentially, the previous 94 entries were flushed because the table only holds 1 entry.

```
! CSR5
logging history
logging history informational
```

```
R5#show logging history
Syslog History Table: 1 maximum table entries,
saving level informational or higher
174 messages ignored, 0 dropped, 0 recursion drops
94 table entries flushed
SNMP notifications not enabled
  entry number 95 : SYS-5-CONFIG_I
    Configured from console by console
    timestamp: 91546549
```

Increasing the table to 5 entries allows 5 logs to be stored. To create 5 syslog messages, I just went into configuration mode and back out several times. Focusing on SNMP briefly, we see that “SNMP notifications are not enabled”. We will rectify this next.

```
! CSR5
logging history size 5

R5#show logging history
Syslog History Table: 5 maximum table entries,
saving level informational or higher
174 messages ignored, 0 dropped, 0 recursion drops
95 table entries flushed
SNMP notifications not enabled
  entry number 96 : SYS-5-CONFIG_I
    Configured from console by console
    timestamp: 91566675
  entry number 97 : SYS-5-CONFIG_I
    Configured from console by console
    timestamp: 91574959
  entry number 98 : SYS-5-CONFIG_I
    Configured from console by console
    timestamp: 91576225
  entry number 99 : SYS-5-CONFIG_I
    Configured from console by console
    timestamp: 91576536
  entry number 100 : SYS-5-CONFIG_I
    Configured from console by console
    timestamp: 91576860
```

To enable SNMP traps to carry syslog messages, these two things must happen. First, logging for SNMP-traps must be enabled, and SNMP traps for syslog must also be enabled in global configuration. Once both of these changes are made, the output indicates that SNMP notifications are now enabled.

```
! CSR5
logging snmp-trap emergencies
logging snmp-trap alerts
logging snmp-trap critical
logging snmp-trap errors
logging snmp-trap warnings
snmp-server enable traps syslog

R5#show logging history | include SNMP
SNMP notifications enabled, 0 notifications sent
```

XR also supports logging history. The configuration is almost identical to XE. I also enable logging at the notification level (5), rather than the informational level (6) just for variety.

```
! XRv1
logging history size 5
logging history notifications
```

```
RP/0/0/CPU0:XRv1#show logging history
Syslog History Table: '5' maximum table entries
saving level 'notice' or higher
0 messages ignored, 0 dropped, 44 table entries flushed
SNMP notifications disabled
```

```
RP/0/0/CPU0:: ntpd[236]: %IP-IP_NTP-5-LP_CONN_RECOVERED : At least a low
priority NTP peer connection was recovered - Stratum 15->8.
[snip, more logs]
```

There is no “logging snmp-trap” command in XR, so to enable SNMP trap logging inside syslog, just enable “snmp-server traps syslog” in global configuration.

```
! XRv1
snmp-server traps syslog
```

```
RP/0/0/CPU0:XRv1#show logging history
Syslog History Table: '5' maximum table entries
saving level 'notice' or higher
0 messages ignored, 0 dropped, 44 table entries flushed
SNMP notifications enabled, 0 notifications sent
[snip]
```

Earlier I mentioned “file” logging was no longer supported, because the feature has been expanded into the “persistent” logging feature. This can write to any URL and has several performance-related parameters that can be tuned. For example, logs can be written immediately or grouped together in batches, the maximum size of each log file can be set, and the total amount of disk space used can be limited. All of these options must be entered at once in one giant command, but it is straightforward to comprehend. On CSR5, I enable this feature; keep in mind the URL destination is a directory designed to contain the log files, not a file itself, so name it accordingly.

```
! CSR5
logging persistent url bootflash:/syslogs size 16384 filesize 16384 immediate
notify
```

```
R5#show logging | include Persist
Persistent logging: enabled, url bootflash:/syslogs, disk space 16384
bytes, file size 16384 bytes, batch size 4096 bytes, threshold capacity 0
, immediate , notify
```

When you use the “notify” keyword as I did, the system prints a syslog telling you that someone issued the “show logging” command. The syslog message below is a result of issuing the “show logging”

command shown above. The “immediate” options writes to the URL immediately, which is nice in a test environment or if syslog messages must be assessed quickly. This comes at a performance penalty since every syslog message will invoke a disk write. Grouping these disk writes is a better option in production environments where syslog messages may be generated regularly.

```
! CSR5
%SYS-6-SHOW_LOGGING: User Unknown has activated the show logging command.
```

We can check the contents of the log directly to see what syslog has added so far.

```
R5#dir bootflash: | include syslogs
275809  drwx                4096  Jul 26 2015 14:16:17 +00:00  syslogs

The equivalent of persistent logging in XR is “archive” logging. Many of the parameters are used to tune size/time parameters, and the URL equivalent just points to a disk location. Beware that the boot device cannot be used as a log destination. XRv only comes with one disk by default, so I had to power off the VM, add a new disk, and then enable logging on disk1. If you try to commit the configuration when disk1 is not available, you get an error also. Lastly, if you try to commit with no device specified at all, you get an error. All three are shown below.

```
! XRv1
logging archive
```

```

device disk0
!!% Invalid argument: Boot device /disk0: cannot be used as archive
destination

! XRv1
logging archive
device disk1
!!% No such file or directory: Failed to get status of the archive device.
Error:No such file or directory

! XRv1
logging archive
severity informational
!!% Invalid argument: Attempting to configure other parameters when mandatory
device configuration is absent

```

Below is a valid configuration. Unfortunately, even after adding the new disk to XRv, it did not recognize the second disk and the configuration was rejected. Just specifying “harddisk” seemed to work, even though it picked disk0.

```

! XRv1
logging archive
device harddisk
severity informational
file-size 2
frequency daily
archive-size 4
archive-length 2

```

XR does not appear to have an “immediate” option, so we are left waiting for the logs to be written to disk. We can generate logs using the exec “logmsg” command. The file has been built in the hd_staging subdirectory but is 0 bytes in length.

```

RP/0/0/CPU0:XRv1#dir | include syslog
63529      drwx  1024      Sun Jul 26 14:30:01 2015  syslog

RP/0/0/CPU0:XRv1#logmsg HELLO
RP/0/0/CPU0: logger[65736]: %OS-SYSLOG-6-LOG_INFO : HELLO

RP/0/0/CPU0:XRv1#dir disk0:/syslog/hd_flush
Directory of disk0:/syslog/hd_flush
No files in directory
2377105408 bytes total (1865272320 bytes free)

```

Inside the hd_staging directory, we find the empty file discussed above.

```

RP/0/0/CPU0:XRv1#dir disk0:/syslog/hd_staging

Logs can also be selectively filtered based on facility, severity, message contents, and other parameters. This feature appears to be broken in XE (perhaps CSR1000v-related) but works on 12.4T. The snippet and verifications are below, but in XE the discriminator doesn't actually work. In this example, I don't want to see the "%SYS-5-CONFIG_I: Configured from console by USER" message on the console line.

```
! CSR5
logging discriminator SYSCFG severity drops 5 facility drops SYS
logging console discriminator SYSCFG
```

```
R5#show logging | section SYSCFG|Console
SYSCFG      severity group drops      5
            facility      drops      SYS
```

```
Console logging: level debugging, 367 messages logged, xml disabled,
                  filtering disabled, discriminator(SYSCFG),
                  0 messages rate-limited, 0 messages dropped-by-MD
```

A quick GNS3 test using 12.4T shows this exact configuration actually works.

```
R1#show logging | section SYSCFG|Console
SYSCFG      severity group drops      5
            facility      drops      SYS
```

```
Console logging: level debugging, 11 messages logged, xml disabled,
                  filtering disabled, discriminator(SYSCFG),
                  0 messages rate-limited, 7 messages dropped-by-MD
```

XR also supports this feature except it is called "logging suppress". You have to memorize a ton of information to know what exactly you are configuring, so I just took an example from Cisco. This will hide the syslog that gets generated when a commit is successful. This doesn't appear to work, though, and Cisco doesn't go into much detail. Cisco also spelled "MGBL" incorrectly in their example. The configuration is shown below and left on XRv1 for reference.

```
! XRv1
logging suppress rule MGBLHIDE
alarm MGBL COMMIT SUCCEDED

logging suppress apply rule MGBLHIDE
all-of-router
```

15. **NTP:** NTP keeps devices time synchronized to help with log analysis. NTP itself must be secured also. There is an entire section dedicated to NTP. This lab takes many of those security techniques, including authentication and access-groups, and applied them to all devices in the SP network as applicable. A quick verification to see if authentication and access-control works is shown here, from CSR6's perspective. Recall that the peer ACL determines who is allowed to update the local clock (should only be authorized servers), and the serve ACL determines to whom you may serve time (clients should never serve time). CSR6 is an NTP client and its configuration is shown below. We can see that packets from CSR10, the NTP master, are permitted by the ACL and authenticated by key 85.

```
! CSR6
ip access-list standard ACL_NTP_PEER
  permit 10.10.10.10
ip access-list standard ACL_NTP_SERVE
  deny any

ntp logging
ntp authentication-key 85 md5 0525323F1E6D7B3D31 7
ntp authenticate
ntp trusted-key 85
ntp source Loopback0
ntp access-group peer ACL_NTP_PEER
ntp access-group serve ACL_NTP_SERVE
ntp server 10.10.10.10 key 85

R6#show ntp associations detail | include master
10.10.10.10 configured, ipv4, authenticated, our_master, sane,valid,stratum 8

R6#show access-list ACL_NTP_PEER
Standard IP access list ACL_NTP_PEER
  10 permit 10.10.10.10 (11 matches)

R6#show access-lists ACL_NTP_SERVE
Standard IP access list ACL_NTP_SERVE
  10 deny any
```

16. **SNMP:** SNMP is used to manage network devices. It should not use default community strings in SNMPv1 and SNMPv2c, and should preferably use SNMPv3 for additional security. ACLs should be put in place to limit read-only and read-write capabilities. In this example, we configure CSR6 with several SNMP features, including version 2c (community based) and version 3 (auth/priv based). The communities are basically passwords used to read or write to a device using SNMP. In this example, I define two communities, one with read-only access, and one with read-write. The access to each is further restricted by ACLs, one for IPv6 and one for IPv4. Generally speaking, the RW ACL should be more restrictive than the RO one.

```
! CSR6
ip access-list standard ACL_SNMP_RO_IPV4
```

```

permit 85.0.0.0 0.255.255.255

ip access-list standard ACL_SNMP_RW_IPV4
permit 85.100.46.57

ipv6 access-list ACL_SNMP_RO_IPV6
permit ipv6 ::85:0:0:0/80 any

ipv6 access-list ACL_SNMP_RW_IPV6
permit ipv6 host ::85:100:F:F any

snmp-server community R6_RO_COMM RO ipv6 ACL_SNMP_RO_IPV6 ACL_SNMP_RO_IPV4
snmp-server community R6_RW_COMM RW ipv6 ACL_SNMP_RW_IPV6 ACL_SNMP_RW_IPV4

```

A more secure way of configuring SNMP is to use version 3. The configuration is much more involved as there is a three-step procedure. First, views should be configured which are essentially permission sets. In my example, I configure two views, one with full permissions and one for a BGP administrator who only needs a handful of rights (similar to RBAC in concept). The “show snmp view” command is very basic and takes no arguments, other than showing you the configured views.

```

! CSR6
snmp-server view ALL iso included
snmp-server view BGP_ADMIN ip included
snmp-server view BGP_ADMIN bgp included
snmp-server view BGP_ADMIN ipForward included

R6#show snmp view | include BGP|ALL
ALL iso - included nonvolatile active
BGP_ADMIN ip - included nonvolatile active
BGP_ADMIN bgp - included nonvolatile active
BGP_ADMIN ipForward - included nonvolatile active

```

The views are bound to groups, which defined the manner in which users authenticate. We create an ADMINS group that requires both authentication and encryption, and has RW permissions. I re-use the ACLs from earlier because, in a migration from v2c to v3, normally the same users would have the same rights they always did. The BGP_GUYS group is less secure, requiring authentication only, but only granting RO rights. The show command takes no arguments and summarizes the group (v3) and community string (v1/v2c) configuration. The “v1default” view is applied automatically to v2c communities and gives full access.

```

! CSR6
snmp-server group ADMINS v3 priv read ALL write ALL access ipv6
ACL_SNMP_RW_IPV6 ACL_SNMP_RW_IPV4

snmp-server group BGP_GUYS v3 auth read BGP_ADMIN access ipv6
ACL_SNMP_RO_IPV6 ACL_SNMP_RO_IPV4

```

```
R6#show snmp group
[snip]
```

```
groupname: ADMINIS                      security model:v3 priv

[snip]
```

It's interesting that we see both v1 and v2c groups for our communities above (not related to v3). SNMP configuration in these platforms is somewhat unintuitive; we have to specify the community as a "group" and remove SNMPv1 as a supported. Even worse, these commands do not show up in the configuration, and must be entered manually. Also notice above that v1 permissions under the RW group did not grant write permission. There are only two fundamental differences between v1 and v2c: introduction of the inform message (discussed in the SNMP traps section) and support for 64-bit

counters. SNMPv2c isn't any more secure than SNMPv1, but disabling v1 support at least minimizes the number of servers that could poll the device using that old version.

```
! CSR6, not retained in configuration
no snmp-server group R6_RO_COMM v1
no snmp-server group R6_RW_COMM v1
```

```
R6#show snmp group | include COMM
groupname: R6_RO_COMM                security model: v2c
groupname: R6_RW_COMM                security model: v2c
```

The SNMPv3 users are defined last and are assigned to groups. The users never show up in the running configuration on XE, so I've pasted the commands for reference; they are very long commands. You can add the ACLs here for additional security so if your credentials are compromised, intruders cannot log in from unauthorized IP addresses. Unlike the other show commands, you can specify the user here.

```
! CSR6
snmp-server user NRUSO ADMINS v3 auth sha AUTHPASS priv aes 256 PRIVPASS
access ipv6 ACL_SNMP_RW_IPV6 ACL_SNMP_RW_IPV4

snmp-server user JLI BGP_GUYS v3 auth sha AUTHPASS access ipv6

Privacy Protocol: AES256
Group-name: ADMINS
```

I've added several other SNMP features, some of which indirectly support security. Setting the source interface to a loopback, and also establishing some QoS value, can be valuable to ensure HA for your SNMP-managed devices. I also configured it to silently discard packets from unknown users. The location, contact, and chassis-ID are just text strings used to identify the device. The last command ensures that the interface ID's assigned persist across a reboot.

```

! CSR6
snmp-server trap-source Loopback0
snmp-server source-interface informs Loopback0
snmp-server drop unknown-user
snmp-server location R6
snmp-server ip dscp 16
snmp-server contact nrusso@r6.net
snmp-server chassis-id R6_CHASSIS
snmp ifmib ifindex persist

```

As expected, the SNMP configuration in XR is similar to XE. XR supports IPv6 DSCP markings, which I set, but does not appear to support both IPv4 and IPv6 ACLs concurrently. You can pick one or the other, so I added IPv4 only. I won't walk through the configuration since it is nearly identical to what was reviewed earlier. Unlike XE, XR displays the users in the configuration with encrypted credentials.

```

! XRv1
ipv4 access-list ACL_SNMP_RO_IPV4

17. **Out-of-band management:** OOBM ensures that if the production network is compromised, you can still manage your devices safely. OOBM implementations can use terminal servers with reverse telnet or an OOBM IP network. In my virtual lab, there is a virtual serial port concentrator (vSPC) running on a Linux VM that connects to each console line of the routers. That is how I manage it, so any data-plane issues should not affect one's ability to manage my device (unless the issue is so serious it hogs all the resources or crashes the router). In real life, even inexpensive layer 2 switches are sufficient for medium-sized OOBM networks since there is very little traffic on it, and it is expected to be stable/redundant. Larger networks may use stacked switches or even routers for OOBM.

49.3 Data plane security best practices

1. **Antispoof ACL:** This is the classic method of ensuring only traffic from legitimate sources can enter a network. Modern networks typically use unicast RPF to handle this automatically. I've coupled this task with the following two tasks since only one ACL can be applied to an interface at one time.
2. **Anti-bogon and RFC1918 ACLs:** These reject traffic that should never be seen on the Internet, which includes private addressing and several other ranges (some are public, but unallocated). This is combined with the antispoof and infrastructure ACL testing.
3. **Infrastructure ACLs (iACL):** These are used to protect the infrastructure networks (links between routers, MPLS LSP loopback endpoints, management LANs, etc). There is no reason why external traffic should ever be destined to (or sourced from) these networks. Normally, unicast RPF (uRPF) is used to protect infrastructure spoofing, which is discussed in detail later. The only exception would be if the transit links are not advertised into IGP, then the ASBRs would never have a route to compare against. I've configured the iACL solution on XRv1 and CSR4 only. After combining the antispoof, RFC1918/bogon, and iACL, the result is shown below. Notice that it closely resembles the bogon route-filter we used earlier, except this is added data-plane protection. I use object-groups to help modularize the configuration, but it makes readability more difficult (more scrolling through the configuration). The idea is that I want to block traffic coming from or going to any combination of these "bad networks". Included in this list, in order to prevent spoofing and protect infrastructure, is the 85.0.0.0/8 network which is used by the SP. Using object-groups this way creates enormous ACLs behind the scenes, which is N^2 entries in this case (N is the number of entries in the object-group). Notice that the ACL must permit critical control-plane traffic; because the BGP session is using an RFC1918 transit link, we need a match higher in the ACL processing sequence to permit that traffic. First, we examine XE configuration on CSR4. These object groups do not support IPv6 at this time.

```
! CSR4
object-group network OBJGRP_BAD_NETS
 0.0.0.0 255.0.0.0
10.0.0.0 255.0.0.0
100.64.0.0 255.192.0.0
127.0.0.0 255.0.0.0
169.254.0.0 255.255.0.0
172.16.0.0 255.240.0.0
192.0.0.0 255.255.255.0
192.0.2.0 255.255.255.0
192.168.0.0 255.255.0.0
198.18.0.0 255.254.0.0
198.51.100.0 255.255.255.0
203.0.113.0 255.255.255.0
224.0.0.0 224.0.0.0
85.0.0.0 255.0.0.0

ip access-list extended ACL_PEER_SP_IN
 permit tcp host 10.1.4.1 host 10.1.4.4 eq bgp
 permit tcp host 10.1.4.1 eq bgp host 10.1.4.4
```

```
deny ip object-group OBJGRP_BAD_NETS object-group OBJGRP_BAD_NETS
permit ip any any
```

```
interface GigabitEthernet2.514
 ip access-group ACL_PEER_SP_IN in
```

A quick test on CSR1 shows that the list is working. We add a route to some RFC1918 addressing and send packets to it. We will also flap the eBGP session with CSR1 to generate legitimate traffic. The BGP traffic is matched by the ACL and passed, while the 50 bogus packets are matched and dropped.

```
! CSR1
ip route 10.0.0.0 255.0.0.0 10.1.4.4
```

```
R1#ping 10.0.0.5 timeout 0 repeat 50
Type escape sequence to abort.
Sending 50, 100-byte ICMP Echos to 10.0.0.5, timeout is 0 seconds:
```

```
.....
Success rate is 0 percent (0/50)
```

```
R4#clear ip bgp 1.1
```

```
R4#show access-l ACL_PEER_SP_IN
Extended IP access list ACL_PEER_SP_IN
 10 permit tcp host 10.1.4.1 host 10.1.4.4 eq bgp
 20 permit tcp host 10.1.4.1 eq bgp host 10.1.4.4 (13 matches)
 30 deny ip object-group OBJGRP_BAD_NETS object-group OBJGRP_BAD_NETS (50
matches)
 40 permit ip any any
```

The configuration on XR is not much different, except that IPv6 is an option also. We configure this on XRv1 to protect the interface facing XRv3.

```
! XRv1
object-group network ipv4 OBJGRP_BAD_NETS
 0.0.0.0/8
 10.0.0.0/8
 85.0.0.0/8
 100.64.0.0/10
 127.0.0.0/8
 172.16.0.0/12
 198.18.0.0/15
 224.0.0.0/3
 169.254.0.0/16
 192.0.0.0/24
 192.0.2.0/24
 192.168.0.0/16
 198.51.100.0/24
 203.0.113.0/24
```

```

ipv4 access-list ACL_PEER_SP_IN
 10 permit tcp host 10.1.3.13 host 10.1.3.11 eq bgp
 20 permit tcp host 10.1.3.13 eq bgp host 10.1.3.11
 30 deny ipv4 net-group OBJGRP_BAD_NETS net-group OBJGRP_BAD_NETS
1000 permit ipv4 any any

interface GigabitEthernet0/0/0/0.513
  ipv4 access-group ACL_PEER_SP_IN ingress

```

On a hardware-based XR platform, this would have worked, but XRv does not support object-groups. I will delete the configuration from XRv1 and leave it here for reference. Instead, I will program a basic ACL just to protect against RFC1918 and infrastructure spoofing.

```

object-group network ipv4 OBJGRP_BAD_NETS
!!% 'obj_group' detected the 'warning' condition 'Object groups not supported
on this platform'

```

```

! XRv1
ipv4 access-list ACL_PEER_SP_IN
 10 permit tcp host 10.1.3.13 host 10.1.3.11 eq bgp
 20 permit tcp host 10.1.3.13 eq bgp host 10.1.3.11
 30 deny ipv4 10.0.0.0/8 any
 40 deny ipv4 172.16.0.0/12 any
 50 deny ipv4 192.168.0.0/16 any
 900 deny ipv4 85.0.0.0/8 any
 910 deny ipv4 any 85.0.0.0/8
1000 permit ipv4 any any

interface GigabitEthernet0/0/0/0.513
  ipv4 access-group ACL_PEER_SP_IN ingress

```

Like earlier, I create a static route on XRv13 to flood RFC1918 traffic in AS 85, and I clear BGP on XRv11 to ensure the BGP session is permitted by the ACL. So far, XE and XR appear to have very similar ACL implementations, which is expected given the fundamental nature of the feature.

```

! XRv3
router static
  address-family ipv4 unicast
    10.0.0.0/8 10.1.3.11

RP/0/0/CPU0:XRv3#ping 10.0.0.5 count 50 timeout 0

RP/0/0/CPU0:XRv1#clear bgp ipv4 unicast as 9.13 soft

RP/0/0/CPU0:XRv1#show access-lists ACL_PEER_SP_IN
ipv4 access-list ACL_PEER_SP_IN
 10 permit tcp host 10.1.3.13 host 10.1.3.11 eq bgp

```

```

20 permit tcp host 10.1.3.13 eq bgp host 10.1.3.11 (7 matches)
30 deny ipv4 10.0.0.0 0.255.255.255 any (50 matches)
40 deny ipv4 172.16.0.0 0.15.255.255 any

900 deny ipv4 85.0.0.0 0.255.255.255 any
910 deny ipv4 any 85.0.0.0 0.255.255.255
1000 permit ipv4 any any

```

4. **Classification ACL:** The ACL ultimately permits all traffic, but by having specific permit statements, you can use the ACE counters to see what traffic is present in your network as a quick troubleshooting technique. External packet capturing tools (Wireshark), Netflow, and EPC would be other options. We will temporarily configure this on CSR8 and XRv2 to measure traffic coming in. I will select some common traffic types to try and narrow down what kind of flows are causing issues.

```

! CSR8
ip access-list extended ACL_PEER_SP_CLASSIFY_IN
 permit icmp any any echo
 permit icmp any any echo-reply
 permit icmp any any unreachable
 permit tcp any any
 permit udp any any
 permit ip any any

interface GigabitEthernet2.518
 ip access-group ACL_PEER_SP_CLASSIFY_IN in

```

We may need to flap BGP so that the routes via CSR8 are oldest from the perspective of AS 1.1. Assuming they are, any eBGP path originating in AS 85 should be reachable via CSR8. We will flood traffic to an arbitrary destination from CSR1. The ACL doesn't block it, so it's possible that the pings may succeed, but the purpose is to measure anomalies. The handful of TCP packets are most likely from the existing eBGP session. The ACL shows 50 new ICMP echo requests. At this point, a more detailed inspection is warranted; the purpose of this feature is to find general anomalies.

```

R1#show ip cef 85.19.16.0
85.19.16.0/20
  nexthop 10.1.8.8 GigabitEthernet2.518

```

```

```

```

R8#show access-lists ACL_PEER_SP_CLASSIFY_IN
Extended IP access list ACL_PEER_SP_CLASSIFY_IN
 10 permit icmp any any echo (50 matches)
 20 permit icmp any any echo-reply
 30 permit icmp any any unreachable
 40 permit tcp any any (9 matches)
 50 permit udp any any
1000 permit ip any any

```

The XR configuration is almost identical. We configure the same ACL in XRv2 facing CSR9.

```
! XRv2
ipv4 access-list ACL_PEER_SP_CLASSIFY_IN
 10 permit icmp any any echo
 20 permit icmp any any echo-reply
 30 permit icmp any any unreachable
 40 permit tcp any any
 50 permit udp any any
1000 permit ipv4 any any

interface GigabitEthernet0/0/0/0.529
 ipv4 access-group ACL_PEER_SP_CLASSIFY_IN ingress
```

This time, we will test from CSR9 into the SP network. We may need to flap BGP so that CSR9 prefers paths via XRv2. We see 50 matches under the proper ACL entry, as expected.

```
R9#show ip cef 85.6.144.0/20
85.6.144.0/20
  nexthop 10.2.9.12 GigabitEthernet2.529
```

```
R9#ping 85.6.144.254 repeat 50 timeout 0
```

```
RP/0/0/CPU0:XRv2#show access-lists ACL_PEER_SP_CLASSIFY_IN
ipv4 access-list ACL_PEER_SP_CLASSIFY_IN
 10 permit icmp any any echo (50 matches)
 20 permit icmp any any echo-reply
 30 permit icmp any any unreachable
 40 permit tcp any any (7 matches)
 50 permit udp any any
1000 permit ipv4 any any
```

5. **Unicast RPF (uRPF):** This is a dynamic, intelligent, and CEF-path mechanism to drop spoofed traffic. If the source of a packet is not reachable via the interface on which the packet was received, the packet is dropped. Since CSR8 and XRv2 do not have any “hard” ACLs applied yet, we will use them for uRPF testing. uRPF operates in two modes: strict and loose. Strict means that a packet arriving on an interface must have the source reachable via that interface, just like multicast RPF. Loose means that a packet arriving on an interface is accepted if there is any valid route out of any interface except null0. This is important for remotely-triggered black holes (RTBH) seen later. We will begin by enabling strict mode on XRv2. Immediately after enabling the feature, we verify the configuration. uRPF has more options in XE than XR, along with better outputs, but we examine XRv2 first. Of note, the “debug ip/ipv6 cef drops rpf” do not work in the CSR1000v, possibly due to it being virtual. Many packet-level debugs relying on CEF do not work, so verification will be done with show commands.

```
! XRv2
```

```
interface GigabitEthernet0/0/0/0.529
  ipv4 verify unicast source reachable-via rx
```

```
RP/0/0/CPU0:XRv2#show ipv4 interface gig0/0/0/0.529 | include RPF
IP unicast RPF check is enabled
RPF mode strict
```

We can test XRv2 by creating an asymmetric routing condition. XRv2 is preferring an iBGP path to CSR1's BGP routes due to AS-path length. If packets sourced from CSR1's routes enter AS 85 from AS 9.13 into XRv2, they should be dropped. You may need to clear CSR9's BGP peering with CSR8 so that XRv2's paths are older, and thus preferred. Let's ensure CSR9 routes through XRv2 to reach the 85 networks, and also verify that XRv2 is routing through CSR4 or CSR8 to each AS 1.1

```
RP/0/0/CPU0:XRv2#show bgp ipv4 unicast 1.12.0.0/16 brief | begin Network
      Network      Next Hop      Metric LocPrf Weight Path
*>i1.12.0.0/16      4.4.4.4          0      100      0 65537 ?
*                   10.2.9.9          0      100      0 589837 65537 ?
* i                 4.4.4.4          0      100      0 65537 ?
```

```
R9#show bgp ipv4 unicast 85.19.4.0/22 bestpath
BGP routing table entry for 85.19.4.0/22, version 35
Paths: (4 available, best #3, table default)
  Advertised to update-groups:
    1          2
  Refresh Epoch 1
  85
    10.2.9.12 from 10.2.9.12 (12.12.12.12)
      Origin incomplete, localpref 100, valid, external, best
      rx pathid: 0, tx pathid: 0x0
```

We temporarily direct CSR1 to route all BGP traffic through AS 9.13 using local preference. CSR1 would have normally preferred either CSR4 or CSR8 to reach AS 85 prefixes, but no longer.

```
! CSR1
route-map RM_LPREF_IN per 10
  set local-preference 200

router bgp 1.1
  address-family ipv4 un
  neighbor 10.1.9.9 route-map RM_LPREF_IN in
```

```
R1#show bgp ipv4 unicast 85.19.4.0/22 bestpath
BGP routing table entry for 85.19.4.0/22, version 260
Paths: (3 available, best #1, table default)
  Advertised to update-groups:
    1
  Refresh Epoch 2
```

9.13 85

```
10.1.9.9 from 10.1.9.9 (9.10.9.9)
  Origin incomplete, localpref 200, valid, external, best
  rx pathid: 0, tx pathid: 0x0
```

From CSR1, we send packets from 1.12.1.1 to 85.19.4.1, which arrive into AS 85 via XRv2, and should fail uRPF. Because uRPF requires CEF, the CEF process keeps track of the counters.

```
R1#ping 85.19.4.1 source 1.12.1.1 timeout 1 repeat 100
[snip]
Success rate is 0 percent (0/100)
```

```
RP/0/0/CPU0:XRv2#show cef ipv4 interface gig0/0/0/0.529 rpf-statistics
Unicast RPF drops 100
```

We will clear the statistics from XRv2, configure loose mode, verify the configuration, and re-test. Because XRv2 has a valid route to the previously-tested IPv4 prefix, we expect the packets to be passed.

```
RP/0/0/CPU0:XRv2#clear cef ipv4 interface gig0/0/0/0.529 rpf-statistics

! XRv2
interface GigabitEthernet0/0/0/0.529
  no ipv4 verify unicast source reachable-via rx
  ipv4 verify unicast source reachable-via any

RP/0/0/CPU0:XRv2#show ipv4 interface gig0/0/0/0.529 | include RPF
IP unicast RPF check is enabled
RPF mode loose
```

As expected, CSR1 is able to ping this remote destination despite the asymmetric routing. XRv2 does not drop these packets since it has a valid route to the destination.

```
R1#ping 85.19.4.1 source 1.12.1.1 timeout 1 repeat 100
[snip]
Success rate is 100 percent (100/100)

RP/0/0/CPU0:XRv2#show cef ipv4 interface gig0/0/0/0.529 rpf-statistics
Unicast RPF drops 0
```

We will run the same tests with IPv6 uRPF on XRv2 to validate that its behavior is identical to IPv4. We need to verify three things to ensure asymmetry: XRv2 routing through CSR4 or CSR8, CSR1 routing through CSR9, and CSR9 routing through XRv2 (in a clock-wise triangle). The same local-preference route-map applied inbound on CSR1 facing CSR9 has been re-used for IPv6 (configuration not shown).

```
RP/0/0/CPU0:XRv2#show bgp ipv6 unicast 2001:1c00:c::/48 brief | begin Network
  Network      Next Hop      Metric LocPrf Weight Path
*>i2001:1c00:c::/48 4.4.4.4      0      100      0 65537 ?
```

```
*                               fd00:10:2:9::9                               0 589837 65537 ?
```

```
R1#show bgp ipv6 unicast 2001:85:6:84::/62
```

```
[snip]
```

```
9.13 85
```

```
FD00:10:1:9::9 (FE80::9) from 10.1.9.9 (9.10.9.9)  
Origin incomplete, localpref 200, valid, external, best  
rx pathid: 0, tx pathid: 0x0
```

```
R9#show bgp ipv6 unicast 2001:85:6:84::/62
```

```
[snip]
```

```
85
```

```
FD00:10:2:9::12 (FE80::12) from FD00:10:2:9::12 (12.12.12.12)  
Origin incomplete, localpref 100, valid, external, best  
rx pathid: 0, tx pathid: 0x0
```

With the routing “correct”, we enable strict-mode uRPF on XRv2 for IPv6. The configuration and verification are identical to IPv4 uRPF.

```
! XRv2  
interface GigabitEthernet0/0/0/0.529  
  ipv6 verify unicast source reachable-via rx
```

```
RP/0/0/CPU0:XRv2#show ipv6 interface gig0/0/0/0.529 | include RPF  
IP unicast RPF check is enabled  
RPF mode strict
```

Using strict mode, we expect the packets sourced from CSR1 to fail, since they follow the path through AS 9.13, while XRv2 prefers to route iBGP through CSR4.

```
R1#ping 2001:85:6:84::1 source 2001:1C00:C::1 repeat 100 timeout 1  
[snip]  
Success rate is 0 percent (0/100)
```

```
RP/0/0/CPU0:XRv2#show cef ipv6 interface gig0/0/0/0.529 rpf-statistics  
Unicast RPF drops 100
```

Clearing the counters and changing to loose-mode, we see the traffic flows through without any drops. This is the expected behavior and mirrors the test conducted for IPv4.

```
RP/0/0/CPU0:XRv2#clear cef ipv6 interface gig0/0/0/0.529 rpf-statistics
```

```
! XRv2  
interface GigabitEthernet0/0/0/0.529  
  no ipv6 verify unicast source reachable-via rx  
  ipv6 verify unicast source reachable-via any
```

```
R1#ping 2001:85:6:84::1 source 2001:1C00:C::1 repeat 100 timeout 1
```

```
[snip]
```

```
Success rate is 100 percent (100/100)
```

```
RP/0/0/CPU0:XRv2#show cef ipv6 interface gig0/0/0/0.529 rpf-statistics
```

```
Unicast RPF drops 0
```

Next, we will test the uRPF features on CSR8. We begin with strict mode on both externally-facing interfaces (AS 1.1 and AS 9.13 links). After configuring the feature, as always, we must verify it. Fortunately, the output is more compact and we get more information from a single command, where XR required more work.

```
! CSR8
```

```
interface GigabitEthernet2.589
```

```
ip verify unicast source reachable-via rx
```

```
interface GigabitEthernet2.518
```

```
ip verify unicast source reachable-via rx
```

```
R8#show ip interface gig2.589 | begin IP_verify
```

```
IP verify source reachable-via RX
```

```
0 verification drops
```

```
0 suppressed verification drops
```

```
0 verification drop-rate
```

```
R8#show ip interface gig2.518 | begin IP_verify
```

```
IP verify source reachable-via RX
```

```
0 verification drops
```

```
0 suppressed verification drops
```

```
0 verification drop-rate
```

Leaving the local-preference 200 route-maps in place on CSR1 towards CSR9, CSR1 prefers AS 9.13 to reach all routes from AS 85. We can clear the BGP peer with XRv2 on CSR9 so that it selects CSR8 as the bestpath for its AS 85 prefixes. CSR8 still believes that CSR1 is the bestpath to reach all AS 1.1 originated prefixes (makes sense since it is a direct peer), yet traffic sourced from those routes will arrive from AS 9.13 where uRPF strict-mode is enabled. We will verify the BGP routing before continuing.

```
R1#show bgp ipv4 unicast 85.6.144.0 bestpath
```

```

```

```

R8#show bgp ipv4 unicast 1.15.0.0 bestpath
BGP routing table entry for 1.15.0.0/16, version 130
Paths: (4 available, best #4, table default)
  Advertised to update-groups:
    20
  Refresh Epoch 2
  65537
    10.1.8.1 from 10.1.8.1 (10.1.8.1)
      Origin incomplete, metric 0, localpref 100, valid, external, best
      rx pathid: 0, tx pathid: 0x0

```

When CSR1 goes to send traffic to AS 85, it will fail uRPF as it arrives on CSR8 from AS 9.13. This is consistent with XRV's uRPF behavior so far.

```

R1#ping 85.6.144.1 source 1.15.1.1 timeout 1 repeat 10
[snip]
Success rate is 0 percent (0/100)

```

```

R8#show ip interface gig2.589 | begin IP_verify
IP verify source reachable-via RX
100 verification drops
0 suppressed verification drops
0 verification drop-rate

```

Changing the interface facing CSR9 to loose-mode, packets arriving along this same path should be accepted. We will clear the counters for cleanliness. Interestingly, we see packets logged as suppressed verification drops. The documentation states that this counter is used for packets that failed uRPF, but were permitted manually by an ACL. I did not apply a "pardon" ACL (discussed later), so I assume this counter also shows packets permitted by loose-mode uRPF that would have failed under strict-mode uRPF conditions.

```

R8#clear ip interface gig2.589 stats

! CSR8
interface GigabitEthernet2.589
  no ip verify unicast source reachable-via rx

```

```
ip verify unicast source reachable-via any
```

```
R1#ping 85.6.144.1 source 1.15.1.1 timeout 1 repeat 100  
[snip]
```

```
Success rate is 100 percent (100/100)
```

```
R8#show ip interface gig2.589 | begin IP_verify  
IP verify source reachable-via ANY  
0 verification drops  
100 suppressed verification drops  
0 verification drop-rate
```

Like with XRv2, we will quickly test IPv6 uRPF on XE. We first need to configure the feature and verify it. Notice that the IPv6 counters differentiate between process and CEF matched packets.

```
! CSR8  
interface GigabitEthernet2.518  
ipv6 verify unicast source reachable-via rx
```

```
interface GigabitEthernet2.589  
ipv6 verify unicast source reachable-via rx
```

```
R8#show ipv6 interface GigabitEthernet2.518 | include verif  
IPv6 verify source reachable-via rx  
0 verification drop(s) (process), 0 (CEF)  
0 suppressed verification drop(s) (process), 0 (CEF)
```

```
R8#show ipv6 interface GigabitEthernet2.589 | include verif  
IPv6 verify source reachable-via rx  
0 verification drop(s) (process), 0 (CEF)  
0 suppressed verification drop(s) (process), 0 (CEF)
```

We quickly verify our BGP routing still forms an asymmetric triangle. CSR1 routes to AS 85 via CSR9, CSR9 routes to CSR8, and CSR8 routes back to AS 1.1 via CSR1. This asymmetry was introduced by the local-preference adjustment made on CSR1 facing CSR9 earlier in the test.

```
R1#show bgp ipv6 unicast 2001:85:6:88::/61  
[snip]  
9.13 85  
FD00:10:1:9::9 (FE80::9) from 10.1.9.9 (9.10.9.9)  
Origin incomplete, localpref 200, valid, external, best  
rx pathid: 0, tx pathid: 0x0
```

```
R9#show bgp ipv6 unicast 2001:85:6:88::/61  
[snip]  
85  
FD00:10:8:9::8 (FE80::8) from 10.8.9.8 (8.8.8.8)  
Origin incomplete, localpref 100, valid, external, best
```

```
rx pathid: 0, tx pathid: 0x0
```

```
R8#show bgp ipv6 unicast 2001:1C00:E::/48
```

```
[snip]
```

```
65537
```

```
FD00:10:1:8::1 from 10.1.8.1 (10.1.8.1)
```

```
Origin incomplete, metric 0, localpref 100, valid, external, best
```

```
mpls labels in/out 8025/nolabel
```

```
rx pathid: 0, tx pathid: 0x0
```

Now, we ping from CSR1 to CSR10 and record the result. All of the packets were uRPF failures dropped by IPv6 CEF. With uRPF operating in strict-mode, this is the expected behavior.

```
R1#ping 2001:85:6:88::1 source 2001:1C00:E::1 timeout 1 repeat 100
```

```
[snip]
```

```
Success rate is 0 percent (0/100)
```

```
R8#show ipv6 interface GigabitEthernet2.589 | include verif
```

```
IPv6 verify source reachable-via rx
```

```
0 verification drop(s) (process), 100 (CEF)
```

```
0 suppressed verification drop(s) (process), 0 (CEF)
```

Next, we will clear the counters (I didn't find a specific command, so I cleared all interface parameters) and enable loose-mode. Upon re-test, all packets succeed, but like IPv4, they are marked as suppressed verification drops as they would have failed the strict uRPF check, but passed only due to loose-mode.

```
R8#clear counters gig2
```

```
interface GigabitEthernet2.589
```

```
no ipv6 verify unicast source reachable-via rx
```

```
ipv6 verify unicast source reachable-via any
```

```
R1#ping 2001:85:6:88::1 source 2001:1C00:E::1 timeout 1 repeat 100
```

```
[snip]
```

```
Success rate is 100 percent (100/100)
```

```
R8#show ipv6 interface GigabitEthernet2.589 | include verif
```

```
IPv6 verify source reachable-via any
```

```
0 verification drop(s) (process), 0 (CEF)
```

```
0 suppressed verification drop(s) (process), 100 (CEF)
```

uRPF can also accept ACLs in XE only. The ACL logic can be thought of like an executive pardon. Despite commit a crime (spoofing), if the ACL permits the packet, it is allowed through anyway. That is why the XE counter calls this a "suppressed" verification, since the RPF drop-action was suppressed. If the ACL also denies it, the packet is dropped normally. Commonly, a deny-any ACL is used with uRPF with logging enabled as this is the only way to log drops from uRPF. In XR, there is no option to log individual packet drops. Only numbered, extended ACLs can be used with uRPF with the current version of XE.

I will demonstrate this using two methods spread across IPv4 and IPv6. The first and most obvious test is, given our still-asymmetric routing, to change CSR8 to do strict-mode uRPF. CSR1 will send packets to a specific network within AS 85 and normally CSR8 would drop it inbound from CSR9, but I will “pardon” spoofed traffic towards that network. This network might be a sinkhole (discussed more later) where the SP wants to attract potential attack traffic for analysis. When verifying this configuration, the ACL numbered is displayed in the show command for completeness.

```
! CSR8
access-list 108 permit ip any 85.6.144.0 0.0.15.255
access-list 108 deny ip any any log-input

interface GigabitEthernet2.589
 ip verify unicast source reachable-via rx 108

interface GigabitEthernet2.518
 ip verify unicast source reachable-via rx 108

R8#show ip interface GigabitEthernet2.589 | begin IP_verify
IP verify source reachable-via RX, ACL 108
 0 verification drops
 0 suppressed verification drops
 0 verification drop-rate
```

When pinging that specific destination from CSR1, the traffic succeeds, and we see matches against suppressed verification drops as expected. This is consistent with Cisco’s documentation; despite strict mode being enabled, this traffic was “pardoned” by a manual ACL. We also see ACL matches; only packets that fail uRPF are subject to the follow-on ACL matching, which is a performance enhancement compared to a traditional inbound ACL.

```
R1#ping 85.6.144.1 source 1.15.1.1 repeat 100 timeout 1
[snip]
Success rate is 100 percent (100/100), round-trip min/avg/max = 1/24/203 ms
```

```
R8#show ip interface GigabitEthernet2.589 | begin IP_verify
IP verify source reachable-via RX, ACL 108
 0 verification drops
100 suppressed verification drops
 0 verification drop-rate
```

```
R8#show access-lists 108
Extended IP access list 108
 10 permit ip any 85.6.144.0 0.0.15.255 (100 matches)
 20 deny ip any any log-input
```

Pinging any other AS 85 destination network, even from the same source, is rejected. We see a log message on CSR8 also. We check the counters to confirm all packets were dropped. When coupled with syslog exportation, logging is a good tool to identify spoofing attacks from a management perspective.

```
R1#ping 85.6.136.1 source 1.15.1.1 repeat 15 timeout 1
[snip]
Success rate is 0 percent (0/15)

%FMANFP-6-IPACCESSLOGDP: F0: fman_fp_image: list 108 denied icmp 1.15.1.1
GigabitEthernet2.589-> 85.6.136.1 (8/0), 1 packet

R8#show ip interface GigabitEthernet2.589 | begin IP_verify
IP verify source reachable-via RX, ACL 108
15 verification drops
100 suppressed verification drops
0 verification drop-rate

R8#show access-lists 108
Extended IP access list 108
10 permit ip any 85.6.144.0 0.0.15.255 (100 matches)
20 deny ip any any log-input (15 matches)
```

We will test IPv6 on CSR8 also, but will do it using a less obvious method. One caveat of loose-mode is that routes recursing to null0 are considered invalid, so if a source has no route or a null0 route, the packet is dropped. Assuming CSR8 wants to avoid sending traffic to and receiving it from certain networks, this is a good technique. With loose-mode on all external interfaces, it protects against spoofing from sources in the null0 route. Based on ordinary routing rules, it prevents the router from forwarding traffic destined to those networks also. In this example, two of CSR1's local networks have been blackholed to Null0. The IPv6 ACL permits traffic sourced from half of those networks (2001:1C00:A::/48) as long as it's destined to a real AS 85 route.

```
! CSR8
ipv6 route 2001:1C00:A::/48 null0
ipv6 route 2001:1C00:B::/48 null0

ipv6 access-list ACL_URPF_PERMIT_IPV6
permit ipv6 2001:1C00:A::/48 2001:85::/32
deny ipv6 any any log-input

interface GigabitEthernet2.589
ipv6 verify unicast source reachable-via any ACL_URPF_PERMIT_IPV6

interface GigabitEthernet2.518
ipv6 verify unicast source reachable-via any ACL_URPF_PERMIT_IPV6
```

We quickly verify that uRPF was configured properly, to include the static null0 routes.

```

R8#show ipv6 interface GigabitEthernet2.589 | include verif
IPv6 verify source reachable-via any, ACL ACL_URPF_PERMIT_IPV6
  0 verification drop(s) (process), 0 (CEF)
  0 suppressed verification drop(s) (process), 0 (CEF)

R8#show ipv6 route static | begin ^S
S   2001:1C00:A::/48 [1/0]
    via Null0, directly connected
S   2001:1C00:B::/48 [1/0]
    via Null0, directly connected

R8#show access-lists ACL_URPF_PERMIT_IPV6
IPv6 access list ACL_URPF_PERMIT_IPV6
    permit ipv6 2001:1C00:A::/48 2001:85::/32 sequence 10
    deny ipv6 any any log-input sequence 20

```

When CSR1 sources traffic from the “A” subnet, the packets succeed. The suppressed verification drop counter increments since these normally would have failed uRPF due to the null0 route, but have been “pardoned” by the ACL.

```

R1#ping 2001:85:19:8::1 source 2001:1C00:A::1 timeout 1 repeat 20
[snip]
Success rate is 100 percent (20/20),

```

```

R8#show ipv6 interface GigabitEthernet2.589 | include verif
IPv6 verify source reachable-via any, ACL ACL_URPF_PERMIT_IPV6
  0 verification drop(s) (process), 0 (CEF)
  0 suppressed verification drop(s) (process), 20 (CEF)

R8#show access-lists ACL_URPF_PERMIT_IPV6
IPv6 access list ACL_URPF_PERMIT_IPV6
    permit ipv6 2001:1C00:A::/48 2001:85::/32 (20 matches) sequence 10
    deny ipv6 any any log-input sequence 20

```

When CSR1 sources traffic from the “B” subnet, the packets are dropped and logged.

```

R1#ping 2001:85:19:8::1 source 2001:1C00:B::1 timeout 1 repeat 12
[snip]
Success rate is 0 percent (0/12)

```

```

! CSR8

  deny ipv6 any any log-input (12 matches) sequence 20
```

The static black-hole routes will be removed before continuing (not shown). Next, we analyze the “l2-src” option on XE. This adds an additional check to ensure the source IP and MAC bindings are correct based on the ARP cache. This is only supported for IPv4 currently and only works with strict-mode. In many cases, switched networks will already be running something like DHCP snooping, IP source guard, and/or DAI, but on transit links between service providers, those features may not be appropriate or supported. We will modify CSR8 on the interface towards CSR1 for this test. The configuration verification does not indicate any special for this feature. Looking at CSR1’s IP/MAC binding, we record the proper value. We are not going to test this feature because it will take a lot of effort with a vSwitch that doesn’t support ethertype filtering to block ARP messages, etc.

```
! CSR8
interface GigabitEthernet2.518
 ip verify unicast source reachable-via rx l2-src 108
```

```
R8#show ip interface GigabitEthernet2.518 | begin IP_verify
IP verify source reachable-via RX, ACL 108
  0 verification drops
  0 suppressed verification drops
  0 verification drop-rate
```

```
R8#show ip arp 10.1.8.1
```

Protocol	Address	Age (min)	Hardware Addr	Type	Interface
Internet	10.1.8.1	210	0050.56a9.1aaa	ARPA	GigabitEth2.518

By default, the default-route cannot be used for the uRPF check. If the uRPF-enabled router only has a default route pointing upstream, all traffic will be dropped in both strict and loose modes. There is an option to allow the default route to be used, and it is supported in both XE and XR for both IPv4 and IPv6. CSR9 will originate an IPv4 default to CSR8 and an IPv6 default to XRv2 (configuration not shown). Then, CSR9 will attempt to send traffic into AS 85 from its transit link to XRv3. This is a unique-local IPv6 address but XRv2 and CSR8 do not have security to protect from this, by design. You may need to flap BGP on CSR9 so that it routes to AS 85 via XRv2.

```
R9#show bgp ipv6 unicast 2001:85:19:8::/61
[snip]
85
  FD00:10:2:9::12 (FE80::12) from FD00:10:2:9::12 (12.12.12.12)
    Origin incomplete, localpref 100, valid, external, best
    rx pathid: 0, tx pathid: 0x0
```

When CSR9 sends traffic, they fail uRPF arriving on XRv2, despite XRv2 having a default route.

```
R9#ping 2001:85:19:8::1 source FD00:10:3:9::9 timeout 1
[snip]
Success rate is 0 percent (0/5)
```

```
RP/0/0/CPU0:XRv2#show cef ipv6 interface gig0/0/0/0.529 rpf-statistics
Unicast RPF drops 5
```

```
RP/0/0/CPU0:XRv2#show cef ipv6 FD00:10:3:9::9
::/0, version 1724, proxy default, internal 0x5000011 0x0 (ptr 0xa13b8074)
[1], 0x0 (0xa1384050), 0xa20 (0xa152c4d8)
local adjacency fe80::9
Prefix Len 0, traffic index 0, precedence n/a, priority 4
via fe80::9, GigabitEthernet0/0/0/0.529, 7 dependencies, weight 0, class
0, bgp-ext [flags 0x6020]
```

We can instruct XRv2 to allow traffic so long as it matches the default-route. This makes uRPF less secure, but is required for some environments. We still have protection against reverse-spoofing attacks where an attacker uses a source address within our infrastructure. uRPF still honors the longest-match, so having a more specific IGP/BGP route internally will cause that traffic to fail as expected. When we retest connectivity from CSR1, we see it is successful.

```
! XRv2
interface GigabitEthernet0/0/0/0.529
ipv6 verify unicast source reachable-via any allow-default
```

```
RP/0/0/CPU0:XRv2#show ipv6 interface GigabitEthernet0/0/0/0.529 | include RPF
IP unicast RPF check is enabled
RPF mode loose, allow default route
```

```
RP/0/0/CPU0:XRv2#clear cef ipv6 interface gig0/0/0/0.529 rpf-statistics
```

```
R9#ping 2001:85:19:8::1 source FD00:10:3:9::9 timeout 1
[snip]
Success rate is 100 percent (5/5)
```

```
RP/0/0/CPU0:XRv2#show cef ipv6 interface gig0/0/0/0.529 rpf-statistics
Unicast RPF drops 0
```

We quickly test the same concept on CSR8. Assuming CSR9 routes through CSR8 to reach AS 85, packets matching the default-route for uRPF are dropped initially. We still have the ACL 108 to “pardon” certain packets and uRPF is operating in strict mode presently.

```
R9#show bgp ipv4 unicast 85.19.4.0/22
[snip]
85
```

```
10.8.9.8 from 10.8.9.8 (8.8.8.8)
  Origin incomplete, localpref 100, valid, external, best
  rx pathid: 0, tx pathid: 0x0
```

```
R9#ping 85.19.4.1 source 10.3.9.9 timeout 1
[snip]
Success rate is 0 percent (0/5)
```

As expected, CSR8 creates a log message and records these drops.

```
! CSR8
%FMANFP-6-IPACCESSLOGDP: F0: fman_fp_image: list 108 denied icmp 10.3.9.9
GigabitEthernet2.589-> 85.19.4.1 (8/0), 1 packet
```

```
R8#show ip interface gig2.589 | begin IP_verify
IP verify source reachable-via RX, ACL 108
  5 verification drops
  0 suppressed verification drops
  0 verification drop-rate
```

```
R8#show access-lists 108
Extended IP access list 108
  10 permit ip any 85.6.144.0 0.0.15.255
  20 deny ip any any log-input (5 matches)
```

We instruct CSR8 to allow the default-route to be used for uRPF, clear counters, and re-test. Everything works as expected. Notice that this does not count as a uRPF “failure”. In loose mode, we saw that if a packet arrives on the “incorrect” interface by strict-mode standards, it is allowed through but the suppressed verification drop counter increments. We are using strict-mode here, and the packet did indeed arrive on the proper interface, despite being from the default-route. uRPF does not log an issue.

```
! CSR8
interface gig2.589
  ip verify unicast source reachable-via rx allow-default 108
```

```
R8#clear counters gig2
```

```
R8#show ip interface gig2.589 | begin IP_verify
IP verify source reachable-via RX, allow default, ACL 108
  0 verification drops
  0 suppressed verification drops
  0 verification drop-rate
```

```
R9#ping 85.19.4.1 source 10.3.9.9 timeout 1
[snip]
Success rate is 100 percent (5/5), round-trip min/avg/max = 1/5/19 ms
```

```
R8#show ip interface gig2.589 | begin IP_verify
```

```
IP verify source reachable-via RX, allow default, ACL 108
0 verification drops
0 suppressed verification drops
0 verification drop-rate
```

The BGP default-route advertisements are removed from the configuration before continuing.

6. **Netflow:** There is an entire section on this topic, so it is discussed briefly here. Netflow captures transit traffic based on fields identified by the administrator. The traffic can then be exported to a collector for further analysis or simply viewed on the CLI as a troubleshooting tool. The feature does not appear to be supported on XRv at all since it is linecard-specific. In this example, both CSR5 and CSR6 have identical Flexible Netflow (FNF) configurations. On their interfaces facing the ASBRs, they capture 100% of the MPLS traffic, 50% of the IPv4 traffic, and 20% of the IPv6 traffic. I use a common NetFlow-v9 collector for all records in this example. Using aliases, an administrator can quickly view this information using commands “nfm”, “nf4”, and “nf6” respectively. I prefer the table format, but when the terminal window is narrow, the record format is best. For demonstration, I enabled packet/byte counter collects on the MPLS record. This can be used like a classification ACL, except more powerful and dynamic.

```
! CSR5 and CSR6
flow record FLOW_RECORD_IPV4
match ipv4 dscp
match ipv4 protocol
match ipv4 source address
match ipv4 destination address
match transport source-port
match transport destination-port
match interface input

flow record FLOW_RECORD_MPLS
match interface input
match mpls label 1 details
match mpls label 2 details
match mpls label 3 details
match mpls label 4 details
collect counter bytes
collect counter packets

flow record FLOW_RECORD_IPV6
match ipv6 dscp
match ipv6 protocol
match ipv6 source address
match ipv6 destination address
match transport source-port
match transport destination-port
match interface input

flow exporter FLOW_EXPORTER_COMMON
```

```

Gi2.515	5007 /6*	0 /0	0 /0	0 /0	101	1
Gi2.515	5001 /6*	0 /0	0 /0	0 /0	183	2
Gi2.515	5006 /0	0 /0	0 /0	0 /0	610	5

7. **Committed Access Rate (CAR):** CAR can be used for on-demand policing of certain traffic using QPPB techniques. BGP can signal (using communities) that traffic for a certain destination should receive some kind of QoS treatment (usually a police action within the context of security) and the edge routers act on it. QPPB is discussed in detail in the QoS section, but we will deploy it here as a security tool. CSR10 will set the community value on specific prefixes when it injects them into BGP; I use a route-map and network statement for this. On ingress, the ASBRs will check their BGP table-policies for specific communities, then set the qos-group marker. Later in the input interface order of operations, MQC occurs, and the qos-group can be matched with policing as an action. In this example, ASBRs XRv1 and CSR4 have a policy that states the following:

- a. Routes with community 85:1024 are policed to 1Mbps
- b. Routes with community 85:2048 are policed to 2Mbps
- c. Routes with community 85:4096 are policed to 4Mbps

The benefit of using prefix-independent QPPB matching policies, such as communities as AS-paths, is that they apply to all AFs. XE does not appear to support IPv6 QPPB at all. The configurations are summarized here; CSR10's community imposition was detailed in the "BGP policy accounting" test since the same communities were used. The remaining QPPB configuration on CSR4 is shown below. This is very similar to the BGP PA test since the same feature set is used for traffic matching. The only significant difference is that we set a qos-group, not a traffic-index.

```
! CSR4
ip community-list standard COML_1MBPS permit 85:1024
ip community-list standard COML_2MBPS permit 85:2048
ip community-list standard COML_4MBPS permit 85:4096

route-map RM_QPPB permit 10
  match community COML_1MBPS
  set ip qos-group 1
route-map RM_QPPB permit 20
  match community COML_2MBPS
  set ip qos-group 2
route-map RM_QPPB permit 30
  match community COML_4MBPS
  set ip qos-group 4

router bgp 85
  address-family ipv4
    table-map RM_QPPB
  address-family ipv6
    table-map RM_QPPB

interface GigabitEthernet2.514
  bgp-policy destination ip-qos-map
```

QPPB is quite involved, so we will verify the key components. First, we verify that the route has the proper community and is being received by the ASBRs from both RRs. Recall that XR automatically distributes communities to iBGP peers, but XE does not.

```
R4#show bgp ipv4 unicast 85.19.8.0/21
BGP routing table entry for 85.19.8.0/21, version 815
Paths: (2 available, best #1, table default)
  Advertised to update-groups:
    13
  Refresh Epoch 1
  Local
    10.10.10.10 (metric 30) from 2.2.2.2 (2.2.2.2)
      Origin IGP, metric 0, localpref 100, valid, internal, best
      Community: 85:1024
      Originator: 10.10.10.10, Cluster list: 2.2.2.2
      rx pathid: 0, tx pathid: 0x0
  Refresh Epoch 1
  Local
    10.10.10.10 (metric 30) from 14.14.14.14 (14.14.14.14)
      Origin IGP, metric 0, localpref 100, valid, internal
      Community: 85:1024
      Originator: 10.10.10.10, Cluster list: 14.14.14.14
      rx pathid: 0, tx pathid: 0
```

Next, ensure the QPPB policy is matching the community properly and applying qos-group 1 to the prefix. If CSR4's routing table doesn't show this setting, this likely indicates a problem with the configuration. Unlike BGP PA, clearing the RIB is not required for qos-group modifications to take effect.

```
R4#show ip route 85.19.8.0
Routing entry for 85.19.8.0/21
  Known via "bgp 85", distance 200, metric 0, qos-group 1, type internal
  Last update from 10.10.10.10 00:04:13 ago
  Routing Descriptor Blocks:
  * 10.10.10.10, from 2.2.2.2, 00:04:13 ago
    Route metric is 0, traffic share count is 1
    AS Hops 0
    MPLS label: none
```

Next, ensure QPPB is enabled on the interface. This completes the QPPB verification.

```
R4#show ip interface gig2.514 | include BGP
BGP Policy Mapping is enabled (output ip-qos-map)
Input features: BGP Policy Map, Access List, MCI Check
```

We quickly define our MQC policy to police based on QG markings, and then apply it inbound to the interface in question. This is nothing new and is not discussed in detail.

```

! CSR4
class-map match-all CMAP_QG_1
  match qos-group 1
class-map match-all CMAP_QG_2
  match qos-group 2
class-map match-all CMAP_QG_4
  match qos-group 4

policy-map PMAP_POLICE_IN
  class CMAP_QG_1
    police 1024000
  class CMAP_QG_2
    police 2048000
  class CMAP_QG_4
    police 4096000

interface GigabitEthernet2.514
  service-policy input PMAP_POLICE

```

We verify that the policy was applied successfully. Here, we can see both QPPB and MQC correctly enabled on the interface as input features.

```

R4#show ip interface gig2.514 | include BGP|QoS
  BGP Policy Mapping is enabled (output ip-qos-map)
  Input features: BGP Policy Map, QoS Classification, Access List, MCI Check

R4#show policy-map interface brief
Service-policy input: PMAP_POLICE_IN
  GigabitEthernet2.514

```

To test it from CSR1, we will remove the local-preference 200 modification we used to test uRPF earlier. CSR1 must route through CSR4 to reach AS 85. You may need to flap BGP on CSR8 so that CSR4 advertises older eBGP routes. Notice that CSR1 has no idea about the qos-group or community settings; communities were not leaked outside of AS 85 and qos-group is always a local-router-only setting.

```

R1#show bgp ipv4 unicast 85.19.8.0/21 bestpath
BGP routing table entry for 85.19.8.0/21, version 532
Paths: (3 available, best #3, table default)
  Advertised to update-groups:
    2
  Refresh Epoch 2
  85
    10.1.4.4 from 10.1.4.4 (4.4.4.4)
      Origin IGP, localpref 100, valid, external, best
      rx pathid: 0, tx pathid: 0x0

```

Pinging from CSR1 to this special destination, we see the packets match the MQC policy and are policed accordingly. Pinging from CSR1 (or any source) to any other destination in AS 85 will not be policed since no other routes have been marked with a special community indicating QoS treatment. Of course, any other MQC-supported action is appropriate here (QoS marking, etc) but the CAR technique is specific using QPPB for policing.

```
R1#ping 85.19.8.1 source 1.14.1.1 repeat 50 timeout 1
[snip]
Success rate is 100 percent (50/50), round-trip min/avg/max = 2/18/26 ms

R1#ping 85.19.4.1 source 1.14.1.1 repeat 150 timeout 1
Success rate is 100 percent (150/150), round-trip min/avg/max = 4/22/129 ms
```

```
R4#show policy-map interface gigabitEthernet 2.514 input
GigabitEthernet2.514
```

```
Service-policy input: PMAP_POLICE_IN
```

```
Class-map: CMAP_QG_1 (match-all)

    conformed 0000 bps, exceeded 0000 bps
```

```
Class-map: CMAP_QG_2 (match-all)
  0 packets, 0 bytes
[snip]
```

```
Class-map: CMAP_QG_4 (match-all)
  0 packets, 0 bytes
[snip]
```

```
Class-map: class-default (match-any)
  157 packets, 18979 bytes
  5 minute offered rate 1000 bps, drop rate 0000 bps
  Match: any
```

We cannot apply MQC policies in XRv at all, so testing the data-plane is impossible. However, I've added the appropriate QPPB configurations on XRv1 that are comparable to CSR4. Like BGP PA on XR, this feature is very similar.

```
! XRv1
```

```

route-policy RPL_QPPB
  if community matches-every (85:1024) then
    set qos-group 1
  elseif community matches-every (85:2048) then
    set qos-group 2
  elseif community matches-every (85:4096) then
    set qos-group 4
  else
    pass
  endif
end-policy

router bgp 85
  address-family ipv4 unicast
    table-policy RPL_QPPB
  address-family ipv6 unicast
    table-policy RPL_QPPB

interface GigabitEthernet0/0/0/0.513
  ipv4 bgp policy propagation input qos-group destination
  ipv6 bgp policy propagation input qos-group destination

```

We will limit the verification to control-plane show commands. First, we verify that the ASBR received the route with the proper communities. Two entries appear, one from each RR.

```

RP/0/0/CPU0:XRv1#show bgp ipv4 unicast community 85:1024 | begin Network
      Network      Next Hop      Metric LocPrf Weight Path
*>i85.19.8.0/21    10.10.10.10          0    100      0 i
* i                10.10.10.10          0    100      0 i

```

Next, we verify the BGP policy is applied to the interface so traffic can have its qos-group set. This information is shown in the FIB, but not in the RIB.

```

RP/0/0/CPU0:XRv1#show cef ipv4 85.19.8.0/21
85.19.8.0/21, version 852, internal 0x5000001 0x0 (ptr 0xa13d30f4) [1], 0x0
(0x0), 0x0 (0x0)
  local adjacency 85.1.5.5
  Prefix Len 21, traffic index 0, precedence n/a, priority 4
  QoS Group: 1
[snip]

```

For completeness, the MQC policy is shown below, but cannot be applied due to XRv limitations.

```

! XRv1
class-map match-all CMAP_QG_1
  match qos-group 1
class-map match-all CMAP_QG_2
  match qos-group 2

```

```
class-map match-all CMAP_QG_4
  match qos-group 4
```

```
policy-map PMAP_POLICE_IN
  class CMAP_QG_1
    police rate 1024000 bps
  class CMAP_QG_2
    police rate 2048000 bps
  class CMAP_QG_4
    police rate 4096000 bps
```

It is safe to assume that if the MQC policy was applied inbound on the outside interface, that traffic destined to this special route would be policed in accordance with the class matching qos-group 1, which specifies a 1 Mbps maximum rate. CSR10 is configured to advertise an IPv6 route with a community requesting a 2 Mbps shaped rate. We will ensure XRv1 sets the proper QoS group. The MQC policy would work automatically without any further modifications to support IPv6. We left an IPv6 QPPB table-map on CSR4 for demonstration purposes, but it doesn't accomplish anything.

```
RP/0/0/CPU0:XRv1#show bgp ipv6 unicast community 85:2048 | begin Network
      Network          Next Hop          Metric LocPrf Weight Path

49.4 Advanced security techniques and features

1. **Sinkholes:** A sinkhole is an advanced technique used to attract traffic, like a magnet. Commonly, this is an isolated part of the SP network that advertises routes in an attempt to fool attackers; a sinkhole is to a network like a honey pot is to a server farm. Often times, “dark IP addresses”, or addresses allocated to a provider but not used, along with RFC1918 address, are originated via static routes and distributed across the topology via BGP. Indiscriminate attacks will follow these routes and into a sinkhole where different analysis tools are used to study the attacks. Netflow and classification ACLs are simple mechanisms, but purpose-built sniffer appliances (intrusion detection systems, etc) are more appropriate in real life. Beware that sinkholes can attract a lot of “junk” traffic, so the sinkhole gateway router should have a few high-speed interfaces to the core and should be a powerful router in general. Rather than make static routes to null0, which would just drop the traffic on the sinkhole gateway, a static route points out to the “analysis LAN” interface (where all the sniffer tools reside) with a bogus MAC address. The switched network will receive Ethernet frames destined to this bogus MAC and no switch will have CAM entries for it, implying it will be flooded as an unknown-unicast frame. A dedicated switched network is usually desired in a sinkhole since it is essentially a quarantine for attacks. CSR3 and CSR7 are sinkhole gateways in this design, where CSR3 attracts all of the unused space in AS 85 using a route to 85.0.0.0/8 and 2001:85::/32, while CSR7 attracts all the other traffic with IPv4/IPv6 default routes. Sinkholes can be deployed in anycast fashion, where they both advertise the same routes, and the network selects the closer one based on local BGP (or possibly IGP, but not recommended) best-path calculations. Both sinkhole gateways define basic FNF policies below, along with the sinkhole LANs and static routes.

```
! CSR3 only
interface GigabitEthernet2.3503
  description SINKHOLE
  encapsulation dot1Q 3503
  ip address 10.0.0.2 255.255.255.252
  ipv6 address FE80::3 link-local
  ipv6 address FD00::1/127

ip route 85.0.0.0 255.0.0.0 GigabitEthernet2.3503 10.0.0.1
ipv6 route 2001:85::/32 GigabitEthernet2.3503 FD00::

arp 10.0.0.1 0000.beef.cafe ARPA
ipv6 neighbor FD00:: GigabitEthernet2.3503 0000.beef.cafe
```

There are a few different sinkhole designs, but the preferred design is the one with a single router. Both CSR3 and CSR7 implement this design. On the sinkhole gateways, we verify their static routes pointing out towards their sniffer VLANs with bogus MAC addresses. We trace the entire route recursion for both IPv4 and IPv6, and also verify the ARP/IPv6 ND bindings, which were statically assigned. It is preferable to use very small subnets for the sinkhole from the perspective of the gateway router, which ensures the route-recursion doesn't point some other way. It also prevents the routing from resolving ARP/ND

entries for sniffer devices, which increases security, as those passive listening devices never need to send receive directed traffic from the network.

```

```

After advertising both the IPv4 and IPv6 sinkhole routes into BGP, let's verify that the ASBRs received them. For brevity we will verify XRv1 and CSR4. Each router has two copies of the path, one from each RR. We can use network statements or redistribution for this; CSR3 will use network statements. We also use "next-hop-self" as needed because no one else in AS 85 will have routes to the bogus static route next-hops.

```

! CSR3
router bgp 85
  address-family ipv4
    network 85.0.0.0
    neighbor 2.2.2.2 next-hop-self
    neighbor 14.14.14.14 next-hop-self
  address-family ipv6
    network 2001:85::/32
    ! next-hop-self inherited from AF_IPV6_LUCAST template

To measure traffic entering the sinkhole, CSR3 will reuse the FNF configuration for IPv4 and IPv6 already configured on CSR5 and CSR6 (records not shown again). This will be applied outbound towards the sinkhole to capture 100% of the traffic. In real life, you would never do this, but since the sinkhole LAN is notional, we confirm the router is forwarding traffic onto that LAN properly. The configuration is shown below without the flow record definitions; just the flow monitors and application of FNF policies.

! CSR3

flow monitor FLOW_MONITOR_IPV4

record FLOW_RECORD_IPV4

flow monitor FLOW_MONITOR_IPV6

record FLOW_RECORD_IPV6

interface GigabitEthernet2.3503

ip flow monitor FLOW_MONITOR_IPV4 output

ipv6 flow monitor FLOW_MONITOR_IPV6 output

From CSR1 and CSR9, we will flood some garbage traffic to fake destinations within AS 85's address block. Regardless of where it enters the AS, it should end up in the sinkhole behind CSR3. Because we are piling many security features on top of each other, I had to remove the ACLs applied to some of the routers so that traffic to infrastructure networks (typically blocked by iACLs) is allowed to enter. As expected, some of the SP security features are mutually exclusive, so having a comprehensive design is important. The FNF output below proves that IPv4 traffic is being sent into the sinkhole LAN.

R1#ping 85.33.44.55 source 1.14.1.1 repeat 100 timeout 0

Once it is complete, we can advertise the default routes into BGP via redistribution. Rather than test this from all routers as we did earlier, we will verify that the ASBR's receive the default route, and then test from CSR1 only. Rather than use "next-hop-self" as CSR3 did, we will manually adjust the next-hops for these redistributed routes to add complexity.

```
! CSR7

```

CSR1 does not have any default-route initially, as seen below, for either IPv4 or IPv6. This is the result of our outbound BGP filtering policies. We would adjust those policies, but advertising default routes between SPs over the Internet is generally not advisable.

```

R1#show ip cef 86.1.2.3
0.0.0.0/0
  no route

R1#show ipv6 cef 2001:86:1:2::3
::/0
  no route

```

Adding a temporary static default on CSR1 pointing to CSR4 solves this. This ensures CSR1 will send all default traffic towards CSR4, which. Upon receipt of this traffic, CSR4 should direct it into the sinkhole. Notice that the first octet is 86, not 85, so rather than go to the “intra-network” sinkhole at CSR3, this should go to the “everything else” sinkhole at CSR7.

```

R1#ping 86.1.2.3 source 1.14.1.1 repeat 30 timeout 0

R1#ping 86.1.2.5 source 1.14.1.1 repeat 30 timeout 0

The default routes are removed from CSR1 before continuing.

2. Remotely triggered blackholes (RTBH) with next-hop modification: Similar to the remote CAR technique using QPPB, BGP communities, and qos-groups, this feature is used to signal ASBRs to drop traffic towards a specific destination. This variation of RTBH is less desirable and more clunky than the community-based version analyzed later. The logic is as follows: a router in the topology originates a BGP route with a next-hop set to 192.0.2.1, for example. All of the ASBRs have a static route to 192.0.2.0/24 pointing to null0. Because BGP cannot advertise a prefix with a null next-hop, this route-recursion technique essentially lets the originating router (the “trigger” router) immediately blackhole all traffic heading towards that destination. This is typically used when a host/subnet is under DDoS attack and it is less damaging to blackhole all traffic to that host/subnet rather than let the attack continue. The time it takes to blackhole all traffic is limited only by iBGP convergence time; given an advertisement-interval default value of 0, this is normally fast. and null0 drop mechanisms happen in CEF on the ASBRs, so there is little to no performance impact on the ASBRs.

The first step is ensuring that all ASBRs have static routes for 192.0.2.0/24 (or any other dummy prefix, but this is commonly used because it’s the “Test-Network”) pointing to null0. For IPv6, I used FD00:FFFF::/32. We verify this on XRv1 and CSR4 for brevity.

```
! CSR4 and CSR8
ip route 192.0.2.0 255.255.255.0 Null0
ipv6 route FD00:FFFF::/32 Null0

! XRv1 and XRv2

Now, any routes (BGP or otherwise) with a next-hop in these null ranges will be dropped. We can create a semi-dynamic mechanism on XRv4 and CSR7, our trigger routers, to handle this. When an administrator configures a static route with a certain tag (99 in this case), BGP redistributes it from static and sets some key attributes. Local-preference is set to a high value to defeat other candidate best-paths in the network. The well-known communities “no-export” or “local-as” are set so the blackhole route does not leak out of the AS or sub-AS, respectively. Most importantly, the next-hop is changed to 192.0.2.1 or FD00:FFFF::1 which causes the route recursion on each ASBR to evaluate to null0. Be careful that any existing static into BGP redistribution is not broken; earlier we used redistribution on CSR7 to advertise a default route for a sinkhole. We need to ensure that functionality does not break in addition to configuring RTBH. The route-maps for IPv4 and IPv6 are identical except for the next-hop change. The first clause matches ordinary static routes that need to be injected into BGP (not shown again), and the second clause is for RTBH routes. The route-map was already applied under the IPv6 AF when redistributing static into BGP, and likewise the IPv4 map is applied under the IPv4 AF.

```
! CSR7
```

```
route-map RM_STATIC_BGP_IPV6 permit 20
```

```
match tag 99
```

```
set local-preference 200
```

```
set community no-export
```

```
set ipv6 next-hop FD00:FFFF::1
```

```
route-map RM_STATIC_BGP_IPV4 permit 20
```

```
match tag 99
```

```
set local-preference 200
```

```
set community no-export
```

```
set ip next-hop 192.0.2.1
```

The XR configuration is similar except uses RPL. Parameterization allows us to reuse the same RPL policy by feeding in different next-hop values when we call the RPL. I show the RPL attachment points for clarity since the next-hops are passed inline, not as part of an RPL construct like a prefix-set.

```
! XRv4
```

```
route-policy RPL_STATIC_TO_BGP ($NHOP)
```

```
if tag is 99 then
```

```
set local-preference 200
```

```
set community (no-export)
```

```
set next-hop $NHOP
```

```
endif
```

```
end-policy
```

```

router bgp 85
  address-family ipv4 unicast
    redistribute static route-policy RPL_STATIC_TO_BGP (192.0.2.1)

  address-family ipv6 unicast
    redistribute static route-policy RPL_STATIC_TO_BGP (FD00:FFFF::1)

```

At this point, any static routes created on CSR7 or XRv4 with a tag of 99 will be blackholed in the entire BGP network. Let's assume that XRv4 is our primary trigger router and, as a matter of policy, we only use CSR7 when XRv4 fails. There is currently a DDoS attack against a server 85.19.16.1/32, but other servers in the subnet are not under attack. CSR1 is currently attacking the server and has reachability.

```

R1#ping 85.19.16.1 source 1.14.1.1
[snip]
Success rate is 100 percent (5/5)

```

Adding a static route to 85.19.16.1/32 locally on XRv4 with tag 99 should ensure this traffic gets black holed from all ASBRs. However, a quick test from CSR1 shows RTBH not working.

```

! XRv4
router static
  address-family ipv4 unicast
    85.19.16.1/32 Null0 tag 99

R1#ping 85.19.16.1 source 1.14.1.1
[snip]
Success rate is 100 percent (5/5)

```

At this point, we can see the drawback of this design; intermediate BGP routers must have a route to the bogus next-hop, so be sure to add the null routes for 192.0.2.0/24 and FD00:FFFF::/32 as needed. This is basic BGP behavior and is not specific to RTBH. If you forget this step, the trigger routers and/or RRs will not have a best-path to the black-hole route and will not advertise it further. Always pay attention if BGP is not advertising routes; it is probably related to next-hop inaccessibility when using this technique.

```

! XRv4
router static
  address-family ipv4 unicast
    192.0.2.0/24 Null0

```

Let's check CSR4 to see if it received the route. We see the route arrived with a next-hop of 192.0.2.1 from XRv4. Continuing the route lookups, this resolves to null0, and the CEF entry for the black-holed route evaluates to null0. External entities can no longer reach this server.

```

R4#show bgp ipv4 unicast 85.19.16.1/32
BGP routing table entry for 85.19.16.1/32, version 824

```

```

  Known via "static", distance 1, metric 0 (connected)
  Routing Descriptor Blocks:
    * directly connected, via Null0
      Route metric is 0, traffic share count is 1
R4#show ip cef 85.19.16.1 255.255.255.255
85.19.16.1/32
  nexthop 192.0.2.1 Null0
```

```
R1#ping 85.19.16.1 source 1.14.1.1
[snip]
Success rate is 0 percent (0/5)
```

We will remove the static route from XRv4 and ensure CSR1 has connectivity back to the network once iBGP converges. This is the procedure to undo the RTBH once the DDoS attack subsides. After connectivity is verified (not shown), add a static route to CSR7 to ensure the backup trigger router works the same way. CSR7 is peered to both XRv4 and CSR2 (RRs), which means CSR2 is going to need a route to 192.0.2.1 in order to select a best-path. Again, this technique makes the RTBH design very unwieldy.

```
! CSR7
ip route 85.19.16.1 255.255.255.255 Null0 tag 99

! CSR2
ip route 192.0.2.0 255.255.255.0 Null0
```

The route arrives from both RRs with a next-hop of 192.0.2.1. This resolves to null0 just like before. It doesn't really matter which route is selected as best since the next-hops are the same.

```

```

```

R1#ping 85.19.16.1 source 1.14.1.1
[snip]
Success rate is 0 percent (0/5)

```

We remove the IPv4 static route from CSR7 to restore network connectivity to the server. Next, we will test IPv6 starting with XRv4. CSR1 has decided to attack 2001:85:6:84::/62, including several hosts on that network. We will blackhole the entire network this time, which implies the local-preference setting will come into effect. Last time, the /32 route had no competitors (longest-match), so BGP path attributes did not matter. Before beginning, ensure that CSR1 can reach the host in that subnet to rule out any routing issues beforehand. CSR1 is considered the attacker in this scenario once again.

```

R1#ping 2001:85:6:84::1 source 2001:1c00:f::1
[snip]
Success rate is 100 percent (5/5),

```

We add the static route to XRv4. Remember that the router needs to have a route to the BGP next-hop, even if it ultimately recurses to null0, so add that also.

```

! XRv4
router static
  address-family ipv6 unicast
    fd00:ffff::/32 Null0
    2001:85:6:84::/62 Null0 tag99

```

When we check the ASBRs, we see two different routes with two different next-hops (and thus two different MPLS labels). The real route from CSR10 is not the best path due to local-preference. This is

why setting a high local-preference is recommended for RTBH routes. However, the next-hop shows XRv4, not the bogus next-hop we initially applied.

```
R8#show bgp ipv6 unicast 2001:85:6:84::/62
[snip]
Local
  ::FFFF:14.14.14.14 from 14.14.14.14 (14.14.14.14)
    Origin incomplete, metric 0, localpref 200, valid, internal, best
[snip]
```

This is because we are using 6PE to tunnel IPv6 over an IPv4/MPLS core. In a somewhat sloppy attempt to manage this dynamically, I apply an RPL to the IPv6 labeled-unicast AF-group to forcibly change the next-hop outbound.

```
! XRv4
route-policy RPL_FORCE_NHOP_CHANGE_IPV6($NHOP)
  if community matches-any (no-export) then
    set next-hop $NHOP
  endif
end-policy

router bgp 85
  af-group AF_IPV6_LUCAST address-family ipv6 labeled-unicast
    route-policy RPL_FORCE_NHOP_CHANGE_IPV6(FD00:FFFF::1) out
```

This does not work; the router complains I am trying to set a next-hop for the wrong AFI.

```
! XRv4
bgp[1046]: %ROUTING-BGP-4-POLICY_NHOP_WRONGAFI : The policy
'RPL_FORCE_NHOP_CHANGE_IPV6(FD00:FFFF::1)' attempted to set a next-hop on
2001:85:6:84::/62 with an unsuitable address type. The next-hop will not be
modified.
```

I also tried setting the next-hop to the IPv4 compatible address for the discard route, seen below. The router gives me the same message.

```
! XRv4
router bgp 85
  af-group AF_IPV6_LUCAST address-family ipv6 labeled-unicast
    route-policy RPL_FORCE_NHOP_CHANGE_IPV6(0::FFFF:192.0.2.1) out

bgp[1046]: %ROUTING-BGP-4-POLICY_NHOP_WRONGAFI : The policy
'RPL_FORCE_NHOP_CHANGE_IPV6(0::FFFF:192.0.2.1)' attempted to set a next-hop
on 2001:85:6:84::/62 with an unsuitable address type. The next-hop will not
be modified.
```

6PE is a special case where the next-hop is initially identified and set as an IPv4 route, and BGP will convert it to IPv6. That is why the router was complaining about having the administrator setting an IPv6 next-hop manually. We simply need to set the same next-hop we did for IPv4 on XRv4, and we don't need our forcible outbound next-hop change. For completeness, we will leave our null route to FD00:FFFF::/32 in the configuration because it will work for ordinary IPv6 unicast in the future.

```
! XRv4
router bgp 85
  address-family ipv6 unicast
    no redistribute static route-policy RPL_STATIC_TO_BGP(0::FFFF:192.0.2.1)
    redistribute static route-policy RPL_STATIC_TO_BGP(192.0.2.1)

  af-group AF_IPV6_LUCAST address-family ipv6 labeled-unicast
    no route-policy RPL_FORCE_NHOP_CHANGE_IPV6(0::FFFF:192.0.2.1) out
```

This technique also fails, and the same message is printed once again.

```
! XRv4
bgp[1046]: %ROUTING-BGP-4-POLICY_NHOP_WRONGAFI : The policy
'RPL_STATIC_TO_BGP(192.0.2.1)' attempted to set a next-hop on
2001:85:6:84::/62 with an unsuitable address type. The next-hop will not be
modified.
```

The next attempt to get this working uses a static RPL (no parameterization, because it won't let parameters beginning with "::"). This is also rejected.

```
! XRv4
route-policy RPL_FORCE_NHOP_CHANGE_IPV6
  if community matches-any (no-export) then
    set next-hop ::ffff:192.0.2.1
  else
    pass
end-policy

router bgp 85
  af-group AF_IPV6_LUCAST address-family ipv6 labeled-unicast
    route-policy RPL_FORCE_NHOP_CHANGE_IPV6 out
```

```
bgp[1046]: %ROUTING-BGP-4-POLICY_NHOP_WRONGAFI : The policy
'RPL_FORCE_NHOP_CHANGE_IPV6' attempted to set a next-hop on 2001:85:6:84::/62
with an unsuitable address type. The next-hop will not be modified.
```

We make one last-ditch attempt, using the same method above with an IPv4 address in the RPL; this actually works. We continue the basic verifications on CSR4 to see that the path to the destination ultimately recurses to null0. Also note that since the BGP-next-hop changed, XRv4 is required to allocate a new label for the prefix.

```

! XRv4
route-policy RPL_FORCE_NHOP_CHANGE_IPV6
  if community matches-any (no-export) then
    set next-hop 192.0.2.1
  else
    pass
  endif

```

The result on CSR1 is a little different now. Earlier, CSR1 still had a route for the IPv4 destination but our ASBR's had longer-match discard routes. This time, since the best-path on the ASBRs has "no-export" set, it is not advertised to any eBGP peers as the output depicts. CSR1 now relies on the 2001:85::/32 route to reach its target, which is a sinkhole route. Nonetheless, the RTBH will drop the traffic at CSR4 and the sinkhole will never see it. Without the sinkhole route, the peer ASBRs wouldn't even have a route in the first place, which is can be thought of as a control-plane-only RTBH approach.

```

R1#show bgp ipv6 unicast 2001:85::/32
[snip]

```

85

```

```

```
R1#ping 2001:85:6:84::1 source 2001:1c00:f::1
[snip]
Success rate is 0 percent (0/5)
```

Next, we remove the trigger static route from XRv4 and re-test using CSR7. Ensure that CSR1 has connectivity to the server again, which validates the SP routing as RTBH is toggled off and on.

```
! XRv4
router static
  address-family ipv6 unicast
    no 2001:85:6:84::/62 Null0 tag99

! R7
ipv6 route 2001:85:6:84::/62 null0 tag 99
```

CSR7 also needs to modify the next-hop outbound versus doing so at the time of redistribution, again due to the 6PE operation. Rather than change the route-map applied to redistribution (that is still valid for IPv6 unicast), I create a new route-map to mimic the forcible RPL created earlier. **Two critical caveats: you must remember to send MPLS labels in each permit clause since there is no explicit labeled-unicast AF within XE. Also, the next-hop must be the IPv6 version of the IPv4 next-hop in XE; the opposite was true in XR.** These inconsistencies make 6PE RTBH a very complex topic when using next-hop adjustments.

```
! CSR7
ip community-list standard COML_NO_EXPORT permit no-export

route-map RM_FORCE_NHOP_CHANGE_IPV6 permit 10
  match community COML_NO_EXPORT
  set mpls-label
  set ipv6 next-hop ::FFFF:192.0.2.1
route-map RM_FORCE_NHOP_CHANGE_IPV6 permit 1000
  set mpls-label
```

Next, we check CSR4 to ensure it learned the black-hole path. Notice that the MPLS label was allocated by CSR7. Again, notice this route is not advertised to CSR1, so CSR1 will rely on the shorter /32 match.

Both XRv4 and CSR2 reflected this route to CSR4, as the local-preference made it both of the RRs best paths.

```

[snip]
Success rate is 100 percent (5/5),
```

Another use of RTBH is to drop traffic for specific sources when coupled with uRPF. In the past examples, our trigger routers injected static routes representing AS 85 destinations so that the ASBRs would drop traffic towards those internal destinations. The trigger routers can also inject black-hole routes representing sources (routes in other ASes, Internet routes, etc). Recall that uRPF requires a valid route back to the source, and null0 routes do not qualify. We will test this on XRv2 where blocking sources behind CSR9 is the goal. We will use XRv4 to trigger the block for IPv4 routes and CSR7 to trigger the block for IPv6 routes in this example. The sources to block are 9.10.0.0/16 and 2001:9000:A::/48, which are known network locations for “attackers”. First, we quickly verify that uRPF is still enabled on XRv2 for both IPv4 and IPv6. The current configuration is valid, as this RTBH source-based technique works with strict or loose uRPF.

```
RP/0/0/CPU0:XRv2#show ipv4 interface gig0/0/0/0.529 | include RPF
IP unicast RPF check is enabled
RPF mode loose

RP/0/0/CPU0:XRv2#show ipv6 interface gig0/0/0/0.529 | include RPF
IP unicast RPF check is enabled
RPF mode loose, allow default route
```

Let’s ensure CSR9 can reach some destinations (we aren’t trying to protect destinations this time, just reject sources) within AS 85. If we don’t verify this first, we may get false negatives since CSR9 won’t be able to send traffic into AS 85 at all. Also ensure CSR9 is routing through XRv2 before testing since that is the uRPF-enforcing router. Currently, connectivity exists as expected.

```
R9#show ip cef 85.19.2.1
85.19.2.0/23
  nexthop 10.2.9.12 GigabitEthernet2.529

R9#show ipv6 cef 2001:85:6:84::1
2001:85:6:84::/62
  nexthop FE80::12 GigabitEthernet2.529

R9#ping 85.19.2.1 source 9.10.9.9
[snip]
Success rate is 100 percent (5/5), round-trip min/avg/max = 1/5/19 ms

R9#ping 2001:85:6:84::1 source 2001:9000:A::9
[snip]
```

Success rate is 100 percent (5/5), round-trip min/avg/max = 4/6/13 ms

Next, we configure the IPv4 trigger route on XRv4, then check XRv2 to see if it was installed as the best-path with the proper next-hop (due to local-preference). We quickly trace the route recursion to verify our configuration.

```
! XRv4
router static
  address-family ipv4 unicast
    9.10.0.0/16 Null0 tag 99

RP/0/0/CPU0:XRv2#show bgp ipv4 unicast 9.10.0.0/16 brief | begin Network

  path-idx 0 NHID 0x0 [0xa13d3cf4 0x0]
  next hop 192.0.2.1 via 192.0.2.0/24
```

Before retesting with the black-hole enabled, we ensure our uRPF counters are cleared out.

```
RP/0/0/CPU0:XRv2#show cef interface gig0/0/0/0.529 rpf-statistics
Unicast RPF drops 0
```

When we test, CSR9 no longer has IPv4 reachability (15 packets sent), and we see the correct number of uRPF failures on XRv2. Because the sources were blocked, CSR9 would try to attack anything inside the AS and be rejected. Once a DoS attacker host is identified, RTBH plus uRPF is an effective technique to prevent all traffic entering the AS from that source.

```
R9#ping 85.19.2.1 source 9.10.9.9 repeat 15 timeout 1
[snip]
Success rate is 0 percent (0/15)
```

```
RP/0/0/CPU0:XRv2#show cef interface gig0/0/0/0.529 rpf-statistics
```

Unicast RPF drops 15

Next, we enable RTBH for the IPv6 source from CSR7. All we have to do is add the static route since the existing RTBH infrastructure has already been built and validated. We then perform our typical verifications on XRv2 to ensure the black-hole route is installed and in use. The 6PE verification on XR is a little awkward for a few reasons. First, the IPv6 next-hop shows as an ordinary IPv4 route, when we know it's really ::FFFF:192.0.2.1. Second, the IPv6 CEF entry shows an unresolved adjacency, but the action is "drop" when looking into the details.

```
! CSR7
ipv6 route 2001:9000:A::/48 null0 tag 99

RP/0/0/CPU0:XRv2#show bgp ipv6 unicast 2001:9000:A::/48 brief | begin Network
      Network      Next Hop      Metric LocPrf Weight Path

[snip]
Success rate is 100 percent (5/5), round-trip min/avg/max = 4/6/14 ms
```

3. Remotely triggered blackholes (RTBH) with communities: The concept of RTBH is identical as the previous section, except this is an alternative and more intelligent design. As we saw earlier, changing the next-hop at the originator (trigger) caused strange issues in the network. First, we had to modify BGP routers so that their best-path algorithms had a route to a bogus next-hop. In addition, we uncovered several inconsistencies between how XE and XR handle 6PE next-hops, and also some complex/interesting RPL parameterization behaviors. Rather than deal with all that unnecessary complexity, the trigger router can set a special community value that signals the ASBRs to locally change the next-hop to something resolving to null0. This ensures the BGP convergence is not affected within the core network (no changes no RRs, etc) and is more consistent with QPPB-based BGP PA and CAR discussed earlier. The only drawback includes more configuration on the ASBRs, which is an inbound RPL/route-map that matches the special community and sets the next-hop. **Using this community-based signaling method is Cisco's recommended RTBH architecture.**

We tested this feature extensively already, so this next set of tests will be limited. Every ASBR has been configured with an RPL or route-map to match the special community (85:98) and set the next-hop to something resolving to null0 (192.0.2.1). Notice that on XR, setting the 6PE next-hop to an IPv4 address is required, but on XE, you must manually compute the IPv4-compatible IPv6 address and set that in the route-map directly.

```
! CSR4 and CSR8
ip community-list standard COML_RTBH per 85:98

route-map RM_RBTH_NHOP_IN per 10
 match community COML_RTBH
 set ip next-hop 192.0.2.1
 set ipv6 next-hop ::FFFF:192.0.2.1
 set local-preference 200
route-map RM_RBTH_NHOP_IN per 10000

router bgp 85
 template peer-policy AF_IPV6_LUCAST
```

```

    route-map RM_RBTH_NHOP_IN in
template peer-policy AF_IPV4_UCAST
    route-map RM_RBTH_NHOP_IN in

! XRv1 and XRv2
route-policy RPL_RBTH_NHOP_IN($NHOP)
    if community matches-any (85:98) then
        set next-hop $NHOP
        set local-preference 200
    else
        pass
    endif
end-policy

router bgp 85
    af-group AF_IPV4_UCAST address-family ipv4 unicast
        route-policy RPL_RBTH_NHOP_IN(192.0.2.1) in
    af-group AF_IPV6_LUCAST address-family ipv6 labeled-unicast
        route-policy RPL_RBTH_NHOP_IN(192.0.2.1) in

```

The trigger routers already have static into BGP redistribution RPL/route-map constructs, so those have been extended to include tag 98, which sets community 85:98 when the route is redistributed. When ASBRs receive their routes, the next-hop modification RPL/route-map is applied inbound for any routes containing that community.

```

! CSR7
route-map RM_STATIC_BGP_IPV4 per 30
    match tag 98
    set community 85:98 no-export

route-map RM_STATIC_BGP_IPV6 per 30
    match tag 98
    set community 85:98 no-export

! XRv4
route-policy RPL_STATIC_TO_BGP($NHOP)
    if tag is 99 then
        [snip]
    elseif tag is 98 then
        set community (85:98, no-export)
    endif
end-policy

```

At this point, all we have to do is add static routes with tag 98 to either XRv4 or CSR7. In this example, CSR7 will trigger an IPv6 black-hole and XRv4 will trigger an IPv4 black-hole.

```

! XRv4
router static

```

```
address-family ipv4 unicast
  85.6.144.0/20 Null0 tag 98
```

```
! CSR7
```

```
ipv6 route 2001:85:6:84::/62 null0 tag 98
```

We will verify XRv2 and CSR8 to ensure both IPv4 and IPv6 routes are being black-holed. For brevity, I will not trace the entire recursion stack as we have done that several times. I use verbose verifications on XE and succinct ones on XR for variation. Also note that these routes have two communities; no-export keeps it within the confederation and 85:98 signals the RTBH.

```

[snip]
Success rate is 100 percent (5/5), round-trip min/avg/max = 1/2/9 ms
```

4. Backscatter traceback: This technique combines many techniques already tested. Specifically, it relies on a combination of sinkholes, RTBH, and ICMP unreachable to determine attack ingress points in the network. It is generally designed to defeat IP spoofing attacks and is another tool for SPs to secure their networks. The feature works as follows: an attacker spoofs traffic into the network, the ASBR or some other core router goes to reply, but since the source is not a routable address, it matches a default route advertised from a sinkhole. Thus, the SP's sinkholes will absorb these unreachable and by examining them, we determine which ASBR sent it (the source) and what the spoofed address was (the destination). The traceback allows an SP to quickly narrow down the ingress point of the spoofed traffic and take action (block it via ACL/RTBH, coordinate with the peer SP, etc).

Because uRPF is used to drop packets in CEF, unreachable are not generated regardless of whether they are enabled on the incoming interface (or the null0 interface). As a result, it appears that this

technique is not compatible with uRPF. For this reason, we will focus the next tests on XRv1 and CSR4 where uRPF is not configured. These routers have ICMP unreachables disabled for IPv4 and IPv6 from an earlier task, so we will enable those again (not shown, since it is a basic task). It is important to police these ICMP unreachables once they are enabled on external interfaces, which was discussed earlier.

CSR1 will be used to spoof traffic into the service provider network. CSR1 tries to guess some of AS 85's infrastructure addresses so it uses destinations within 85.0.0.0/8. These unreachables originated by the ASBR as a result of the ACL deny entry will end up in CSR3's sinkhole as it attracts all unknown traffic within 85.0.0.0/8. We rely on the inbound ACL to send the unreachables. CSR1 uses a new Loopback85 to spoof traffic from 85.111.111.111. This will be denied by the ACL with an unreachable sent towards CSR3.

```
R4#show ip cef 85.111.111.111
85.0.0.0/8
  nexthop 85.4.6.6 GigabitEthernet2.546 label 6003

R4#show ip route 85.0.0.0 255.0.0.0

```

When CSR1 starts sending traffic, CSR4 denies those packets and sends unreachables into the sinkhole. Normally, a single unreachable is all that is required, even if CSR1 sent many thousands of spoofed packets within a flow. We check CSR4 for ACL matches and also check the sinkhole. The result of the FNF cache on CSR3 shows that the unreachable came from CSR4 destined to a spoofed source, which helps narrow down ingress points during a DDoS attack when there are several ASBRs in the network. Notice the source address of the unreachable generated by CSR4; it's the transit link between CSR4 and CSR6. Unfortunately, this doesn't tell us from which external interface the spoofed packets arrived. It only narrows down the ASBR. Once logged into the ASBR, however, checking the ACL counters or other classification tools can identify the proper external interface.

```
! CSR1

```

The same technique can be used for IPv6 and on XR, again assuming ICMPv6 unreachables are enabled. This test will be conducted on XRv1 with XRv3 as the attacker. Because ACLs are a simple topic and I did not test this earlier, I created a very weak ACL on XRv1 just to deny some traffic so the router will generate ICMP unreachables. I am blocking traffic sourced from AS 85's address space (spoofed) and unique local addressing.

```

! XRv1
ipv6 access-list ACL_PEER_SP_IN_IPV6
 10 deny ipv6 2001:85::/32 any
 20 deny ipv6 fc00::/7 any
 30 permit ipv6 any any

```

XRv3 will be the attacker in this scenario. First, ensure XRv3 can reach an AS 85 destination from valid sources to check for routing issues.

```

RP/0/0/CPU0:XRv3#ping 2001:85:19:2::1 source 2001:3000:b::13
[snip]
Success rate is 100 percent (5/5), round-trip min/avg/max = 1/6/19 ms

```

XRv3 uses Loopback100 which has two usable IPv6 addresses for spoofing, FC00::13 and 2001:85::13. A quick CEF check on XRv1 indicates the unreachables sent back to these bogus sources will go to the CSR7 and CSR3 sinkholes, respectively. We also check the ACL to see that nothing has been blocked yet.

```

RP/0/0/CPU0:XRv1#show cef ipv6 FC00::13

(0x0), 0x208 (0xa152c460)
Prefix Len 32, traffic index 0, precedence n/a, priority 4
via ::ffff:3.3.3.3, 3 dependencies, recursive [flags 0x6000]
[snip]
```

```
RP/0/0/CPU0:XRv1#show access-lists ipv6 ACL_PEER_SP_IN_IPV6
ipv6 access-list ACL_PEER_SP_IN_IPV6
 10 deny ipv6 2001:85::/32 any
 20 deny ipv6 fc00::/7 any
 30 permit ipv6 any any (3 matches)
```

XRv3 starts sending traffic into the network using spoofed addresses. Because the source originates from an AS 85 network, it will end up in CSR3's sinkhole. XRv1 also has ACL matches for it. The nice thing about XR is that the source address of the unreachable is the interface upon which it was generated (the link facing XRv3). This is more valuable than XE where the IP address source was the outgoing interface (in the core). If XRv1 had 100 eBGP peers, this narrows it down significantly. IP protocol number 58 refers to IPv6-ICMP and is also revealed in the FNF cache.

```
RP/0/0/CPU0:XRv3#ping 2001:85:19:2::1 source 2001:85::13
[snip]

```

5. Lawful intercept: The LI feature is used to comply with Government regulations and laws that require a carrier to tap into customer/transit traffic. All it really entails is enabling the feature via AAA, then allowing the routing to be controlled via SNMPv3. An authorized user will use SNMPv3 to read/write LI information using an external device as needed. I configured this on CSR7 because AAA was already enabled there. SNMP was discussed in detail earlier in this section, so the security settings for this are low for demonstration purposes. Normally one would want LI permissions to be very high since misuse of LI permissions is highly undesirable. One caveat of this feature is that SNMP traps normally sent to port 162 must be sent to port 161. The list of traps specified are in accordance with the Cisco configuration guide and RFC 1157. The SNMP-server target address for traps is the LI mediation device. The LI mediation device is provided by a third-party vendor that handles most of the processing and does several things: provides interface to setup and provision LI, generates requests to other network devices to use LI, and converts traffic intercept by LI into the format required by a specific law enforcement agency (LEA). Traffic is sent from the mediation device to the LEA without the target's knowledge.

```

! CSR7
aaa new-model
aaa intercept
snmp-server group LI_GROUP v3noauth read LI_GROUP write LI_GROUP
snmp-server view LI_VIEW ciscoIpTapMIB included
snmp-server view LI_VIEW cisco802TapMIB included
snmp-server view LI_VIEW ciscoTap2MIB included
snmp-server user LI_USER LI_GROUP v3 auth md5 LI_PASSWORD
snmp-server enable traps snmp authentication linkdown linkup coldstart
warmstart
snmp-server host 10.10.10.10 version 3 noauth LI_USER udp-port 161

```

LI does not appear to be supported on XRv, but we can configure the SNMPv3 parameters anyway.

```

RP/0/0/CPU0:XRv2 (config) #law?
^

```

```
% Invalid input detected at '^' marker.
```

```
! XRv2
snmp-server host 10.10.10.10 traps version 3 noauth LI_USER udp-port 161
snmp-server user LI_USER LI_GROUP v3 auth md5 encrypted
072308737E282A36203D3928
snmp-server view LI_VIEW ciscoTap2MIB included
snmp-server view LI_VIEW ciscoUserConnectionMIB included
snmp-server group LI_GROUP v3 noauth read LI_GROUP write LI_GROUP
snmp-server traps snmp linkup
snmp-server traps snmp linkdown
snmp-server traps snmp coldstart
snmp-server traps snmp warmstart
snmp-server traps snmp authentication
```

The configuration won't commit since the XRv does not appear to have the proper MIBs handy, but the configuration above is valid. The remainder of the configuration, minus the two MIB commands below, is committed for reference.

```
! XRv2
snmp-server view LI_VIEW ciscoTap2MIB included
!!% A verifier or EDM callback function returned: 'invalid argument (NULL
pointer?): SNMP oid subtree ciscoTap2MIB is not part of a known MIB module

snmp-server view LI_VIEW ciscoUserConnectionMIB included
!!% A verifier or EDM callback function returned: 'invalid argument (NULL
pointer?): SNMP oid subtree ciscoUserConnectionMIB is not part of a known MIB
module
end
```

6. BGP Flowspec: BGP Flowspec was defined in its own chapter where I discussed the basic capabilities. It is generally used to provide finer granularity to RTBH and QPPB allowing us to police, remark, redirect to VRF, or drop traffic. We can also look at details such as fragments, layer 4 information, and ICMP type/code on some platforms (CRS, but not ASR9K). I will quickly enable BGP flowspec for the IPv4 and IPv6 address families throughout the topology. Note that XE 3.13.2S only provides RR support for BGP flowspec, so the only XE router being configured with BGP flowspec AF will be CSR2. XE 3.15S introduced support for flowspec in the data plane but is not examined here.

```
! CSR2
router bgp 85
address-family ipv4 flowspec
  neighbor 11.11.11.11 activate
  neighbor 11.11.11.11 route-reflector-client
  neighbor 12.12.12.12 activate
  neighbor 12.12.12.12 route-reflector-client
address-family ipv6 flowspec
  neighbor 11.11.11.11 activate
```

```

neighbor 11.11.11.11 route-reflector-client
neighbor 12.12.12.12 activate
neighbor 12.12.12.12 route-reflector-client

! XRv14
router bgp 85
address-family ipv4 flowspec
address-family ipv6 flowspec

af-group AF_IPV4_FLOW address-family ipv4 flowspec
route-reflector-client
af-group AF_IPV6_FLOW address-family ipv6 flowspec
route-reflector-client

neighbor 11.11.11.11
address-family ipv4 flowspec
use af-group AF_IPV4_FLOW
address-family ipv6 flowspec
use af-group AF_IPV6_FLOW

neighbor 12.12.12.12
address-family ipv4 flowspec
use af-group AF_IPV4_FLOW
address-family ipv6 flowspec
use af-group AF_IPV6_FLOW

! XRv1 and XRv2
router bgp 85
address-family ipv4 flowspec
address-family ipv6 flowspec

neighbor 2.2.2.2
address-family ipv4 flowspec
address-family ipv6 flowspec

neighbor 14.14.14.14
address-family ipv4 flowspec
address-family ipv6 flowspec

```

Configuration-wise, the “client”, or receiver of a BGP flowspec policy, does not need any special BGP configuration other than a flowspec-enabled peer. In most designs, this would be the ASBRs and RRs. Up to this point, that is all we have configured, and since flowspec is a negotiated AF, we should verify successful negotiation. Doing this on the route-reflectors makes the most sense because they can tell us if the negotiation was bidirectionally successful (advertised and received).

```

R2#show bgp neighbors 11.11.11.11 | include Flowspec:
    Address family IPv4 Flowspec: advertised and received
    Address family IPv6 Flowspec: advertised and received

```

```

R2#show bgp neighbors 12.12.12.12 | include Flowspec:
    Address family IPv4 Flowspec: advertised and received
    Address family IPv6 Flowspec: advertised and received

RP/0/0/CPU0:XRv4#show bgp neighbor 11.11.11.11 | include Flowspec:
    Address family IPv4 Flowspec: advertised and received
    Address family IPv6 Flowspec: advertised and received

RP/0/0/CPU0:XRv4#show bgp neighbor 12.12.12.12 | include Flowspec:
    Address family IPv4 Flowspec: advertised and received
    Address family IPv6 Flowspec: advertised and received

```

We will use XRv4 as our flowspec policy “server” for IPv4 and IPv6 since it is central to the network. CSR2 won’t really be doing anything in this capacity but we at least show that its flowspec RR capability works. The flowspec policy configuration is very similar to MQC except the class-maps are of type “traffic”. Additionally, you cannot nest class maps, so the policies are somewhat limited in their hierarchy at this time. Below are some sample class maps with a policy-map to define their actions. I used variety in my matching statements as a demonstration. We use a combination of network address, TCP port, and fragment-type matching techniques. The policy performs a combination of QoS marking, policing, dropping, and VRF redirecting actions.

```

! XRv4
class-map type traffic match-all CMAP_TRAF_AS_9_13_TO_US
    match destination-address ipv4 85.0.0.0 255.0.0.0
    match source-address ipv4 13.0.0.0 255.0.0.0

class-map type traffic match-all CMAP_TRAF_POLICE_TELNET
    match protocol tcp
    match destination-port 23

class-map type traffic match-all CMAP_TRAF_DROP_FRAGMENTS
    match fragment-type is-fragment

class-map type traffic match-all CMAP_TRAF_AS_9_13_TO_US_IPV6
    match destination-address ipv6 2001:85::/32
    match source-address ipv6 2001:9000::/32

policy-map type pbr PMAP_PBR_FLOWSPEC
    class type traffic CMAP_TRAF_AS_9_13_TO_US
        set dscp cs1

    class type traffic CMAP_TRAF_AS_9_13_TO_US_IPV6
        redirect ipv6 nexthop vrf ANALYZE

    class type traffic CMAP_TRAF_DROP_FRAGMENTS
        drop

```

```
class type traffic CMAP_TRAF_POLICE_TELNET
  police rate 1024000 bps
```

XRv does not support data-plane flowspec operations since binding this flowspec policy to BGP requires the flowspec process to exist. It doesn't, and neither do its show commands; this is because XRv represents an RSP with no linecards. The idea is that this policy could be distributed to clients, like the ASBRs XRv1 and XRv2, and ultimately programmed into their hardware linecards as a remote-PBR type of operation. The feature is also VRF aware, as seen in the policy-map actions, assuming it works.

```
RP/0/0/CPU0:XRv4(config)#flo?
      ^
% Invalid input detected at '^' marker.

RP/0/0/CPU0:XRv4#show flo?
      ^
% Invalid input detected at '^' marker.
```

7. BGPsec: Most of the configuration relating to BGPsec revolves around the Resource Public Key Infrastructure (RPKI) server configuration. Cisco routers are generally clients in this architecture. Having this RPKI information allows the routers to perform Origin AS validation to determine what routes are legitimate and which are not. Bestpath-wise, valid routes are always preferred over invalid routes and those without any AS-validation attributes. By default, invalid routes are not candidate for bestpath at all, but this can be disabled. Routes with no attributes are still valid but cannot be considered for bestpath or multipath if there is a valid AS-origin route. Rather than have every single router connect directly to the third-party RPKI server, Cisco routers can distribute this information inside iBGP using extended communities. **This can never be exchanged over eBGP, similar to the cost-community, as it is non-transitive.** In this example, CSR2 and XRv4 are logical choices (RRs) to connect directly to our notional RPKI server, and then distribute that information to other peers via extended-communities. XE devices need to explicitly enable extended-community exchange between each other, while XR does this automatically for iBGP peers (configuration not shown). The RPKI server configuration is shown for CSR2 and XRv4, assuming we have IPv4 and IPv6 RPKI servers in our network. The routers also distribute the AS-origin information to their iBGP peers inside extended-communities for both IPv4 unicast and IPv6 address-families. XR also supports using SSH to communicate with the RPKI server for extra security, but XE does not.

```
! CSR2
router bgp 85
  bgp rpki server tcp ::10:10:99:99 port 5006 refresh 3600
  bgp rpki server tcp 10.10.99.99 port 5000 refresh 3600

  template peer-policy AF_IPV4_UCAST
    announce rpki state
  template peer-policy AF_IPV6_LUCAST
    announce rpki state
```

```

!XRv4
router bgp 85
  rpki server 10.10.99.99
    transport tcp port 5000
    refresh-time 3600

  rpki server ::10:10:99:99
    username RPKI_XRV4
    password RPKI_XRV4
    transport ssh port 5022
    refresh-time off

  bgp origin-as validation signal ibgp
  address-family ipv4 unicast
    bgp origin-as validation signal ibgp

  address-family ipv6 unicast
    bgp origin-as validation signal ibgp

```

I do not show the basic RPKI configuration on all the other iBGP routers within AS 85, but I have enabled transmission of both standard and extended communities, as well as RPKI state propagation. This is somewhat similar to the basic BGP flowspec configuration where all routers must be configured to support it, at a minimum. We will perform some basic verification on both routers to ensure the configuration was successful. Since the RPKI servers do not exist, we won't see any session statistics or any prefixes from them.

```

R2#show bgp ipv4 unicast rpki servers
BGP SOVC neighbor is ::10:10:99:99/5006 connected to port 5006

```

Looking at CSR7, we see that all of the local routes (originating from our own AS) are automatically considered valid. The “V” in the leftmost column means valid; using a regex to only look for local routes helps prove this.

```
R7#show bgp ipv4 unicast quote-regexp "^$" | begin Network
      Network      Next Hop      Metric LocPrf Weight Path
V*> 0.0.0.0        7.7.7.7          0         32768 ?
V* i 10.10.10.85/32 10.10.10.10       0        100      0 ?
V*>i              10.10.10.10       0        100      0 ?
V* i 85.0.0.0      3.3.3.3          0        100      0 i
V*>i              3.3.3.3          0        100      0 i
V* i 85.6.128.0/22 10.10.10.10       0        100      0 ?
V*>i              10.10.10.10       0        100      0 ?
V* i 85.6.132.0/22 10.10.10.10       0        100      0 ?
V*>i              10.10.10.10       0        100      0 ?
```

Examining one of the paths, we see some additional information. Each path has a new extended community of 0x4300, which represents the RPKI state. The last digit represents the validity: 0 means valid, 1 means not-found, and 2 means invalid. In this case, the digit is zero because it is valid, and in case you don’t remember the codes, the output tells you the RPKI state in plain English also.

```
R7#show bgp ipv4 unicast 85.6.128.0/22 bestpath
BGP routing table entry for 85.6.128.0/22, version 174
Paths: (2 available, best #2, table default)
  Not advertised to any peer
  Refresh Epoch 11
  Local
    10.10.10.10 (metric 20) from 2.2.2.2 (2.2.2.2)
      Origin incomplete, metric 0, localpref 100, valid, internal, best
      Extended Community: 0x4300:0:0
      Originator: 10.10.10.10, Cluster list: 2.2.2.2
      path 7F8D84CAEE58 RPKI State valid
      rx pathid: 0, tx pathid: 0x0
```

If we look at any path from another AS, we see the path is marked with an “N” for not-found. Because the path is external, we cannot guarantee the AS path is accurate. Peer ASes could have easily injected false AS path information, and this is the problem BGPsec/RPKI attempt to solve.

```
R7#show bgp ipv4 unicast quote-regexp "^[0-9]+$" | begin Network
      Network      Next Hop      Metric LocPrf Weight Path
N* i 1.10.0.0/16    4.4.4.4          0      100      0 65537 ?
N*>i              4.4.4.4          0      100      0 65537 ?
N* i 1.11.0.0/16    4.4.4.4          0      100      0 65537 ?
N*>i              4.4.4.4          0      100      0 65537 ?
N* i 1.12.0.0/16    4.4.4.4          0      100      0 65537 ?
N*>i              4.4.4.4          0      100      0 65537 ?
```

Looking deeper, we see the same extended community with the last digit as a 1, meaning “not-found”. The RPKI state also makes this clear.

```
R7#show bgp ipv4 unicast 1.11.0.0/16 bestpath
BGP routing table entry for 1.11.0.0/16, version 230
Paths: (2 available, best #2, table default)
  Not advertised to any peer
  Refresh Epoch 11
  65537
    4.4.4.4 (metric 20) from 2.2.2.2 (2.2.2.2)
      Origin incomplete, metric 0, localpref 100, valid, internal, best
      Extended Community: 0x4300:0:1
      Originator: 4.4.4.4, Cluster list: 2.2.2.2
      path 7F8D84CAEC58 RPKI State not found
      rx pathid: 0, tx pathid: 0x0
```

Recalling the rules about best-path selection, valid paths are always preferred over not-found or invalid ones. We do not have a mechanism to test this since all paths with any non-local AS-path will be “not-found”, and any local paths will be valid. However, we can ignore this behavior and let BGP do its normal calculation to ignore these values. As a compromise, we can match the RPKI states in a route-map, and then adjust BGP parameters. A common approach would be to increase local-preference for valid routes and reduce it for invalid ones, which allows invalid routes to be considered for best-path as a last resort. I illustrate this technique on CSR10; the path-selection here is less relevant and I don’t want to break the network testing a feature half-heartedly. In this example, I will adjust local-preference as follows:

- a. Valid routes will all get local-preference 150
- b. Not-found routes will get local-preference 95
- c. Invalid routes will get local-preference 50

The reason I adjust “not-found” routes is because I want to demonstrate that the route-map actually works. I will test this on 6PE routes specifically. A quick check shows the default local-preference of 100 for this route from AS 1.1. Nothing has been adjusted yet.

```

R10#show bgp ipv6 unicast 2001:1C00:A::/48
BGP routing table entry for 2001:1C00:A::/48, version 3815
Paths: (1 available, best #1, table default)
  Not advertised to any peer
  Refresh Epoch 1
  65537
    ::FFFF:4.4.4.4 (metric 30) from 14.14.14.14 (14.14.14.14)
      Origin incomplete, metric 0, localpref 100, valid, internal, best
      Extended Community: 0x4300:0:1
      Originator: 4.4.4.4, Cluster list: 14.14.14.14
      mpls labels in/out nolabel/4028
      path 7F760E6DB020 RPKI State not found
      rx pathid: 0, tx pathid: 0x0

```

The configuration on CSR10 is below and is very straightforward.

```

! CSR10
route-map RM_SET_LPREF_RPKI permit 10
  match rpki valid
  set local-preference 150
route-map RM_SET_LPREF_RPKI permit 20
  match rpki not-found
  set local-preference 95
route-map RM_SET_LPREF_RPKI permit 30
  match rpki invalid
  set local-preference 50

router bgp 85
  template peer-policy AF_IPV6_LUCAST
  route-map RM_SET_LPREF_RPKI in

```

Checking the BGP RIB again for 6PE routes, we see the not-found routes have a new local-preference. This proves that the route-map “match rpki” command works.

```

R10#show bgp ipv6 unicast 2001:1C00:A::/48
BGP routing table entry for 2001:1C00:A::/48, version 3867
Paths: (1 available, best #1, table default)
  Not advertised to any peer
  Refresh Epoch 1
  65537
    ::FFFF:4.4.4.4 (metric 30) from 14.14.14.14 (14.14.14.14)
      Origin incomplete, metric 0, localpref 95, valid, internal, best
      Extended Community: 0x4300:0:1
      Originator: 4.4.4.4, Cluster list: 14.14.14.14
      mpls labels in/out nolabel/4028
      path 7F760E6DB020 RPKI State not found
      rx pathid: 0, tx pathid: 0x0

```

Additionally, we can instruct CSR10 to allow invalid-prefixes as a last resort, given the route-map designed to make them less preferable. This is applied to IPv6 AFI given the configuration below. For completeness, CSR10 will completely ignore the BGPsec feature for the IPv4 AF from the perspective of the best-path selection process; it still retains the “announcement” configurations so that it can support other peers using BGPsec. Manipulating the best-path algorithm in this way can give variable levels of importance to the RPKI state for a prefix.

```
! CSR10
router bgp 85
  address-family ipv6 unicast
    bgp bestpath prefix-validate allow-invalid
  address-family ipv4 unicast
    bgp bestpath prefix-validate disable
```

For completeness, I created an RPL on XRv4 to do the same thing as the route-map did on CSR10, but I did not apply it anywhere. This is for reference only to compare the XE/XR configurations. For variety, rather than match invalid at the end, I used an ordinary else statement. It has the same effect in this case, since there are only three possible states currently.

```
! XRv4
route-policy RPL_SET_LPREF_RPKI
  if validation-state is valid then
    set local-preference 150
  elseif validation-state is not-found then
    set local-preference 95
  else
    set local-preference 50
  endif
end-policy
```

XR allows you to create Route Origin Authorizations (ROAs) that associate a prefix with an AS number. Normally, the authoritative RPKI server would do this and advertise it to routers via BGP. Here, you specify the aggregate prefix, and then the longer prefix length allowed (sort of like a prefix-list), along with the AS. These fields comprise the “resources” with an ROA. XRv4 introduces 85.0.0.0/8 with a max prefix length of 24, originated in AS 85. This means the AS can originate 85.0.128.0/23, 85.0.130.0/24, but not 85.0.131.0/25, since shorter prefixes are generally undesirable on the Internet. XRv4 also validates 2001:85::/32 in the same manner with a maximum prefix length of 96.

```
! XRv4
router bgp 85
  rpk route 85.0.0.0/8 max 24 origin 85
  rpk route 2001:85::/32 max 96 origin 85
```

```
RP/0/0/CPU0:XRv4#show bgp rpk table ipv4
```

Network	Maxlen	Origin-AS	Server
85.0.0.0/8	24	85	0.0.0.0

```
RP/0/0/CPU0:XRv4#show bgp rpki table ipv6
```

Network	Maxlen	Origin-AS	Server
2001:85::/32	96	85	0.0.0.0

I also add some eBGP prefixes to XRv1, specifically encompassing routes from CSR1 and XRv3. The entry for CSR1 is invalid intentionally (notice the incorrect ASN highlighted) while the entry for XRv3 is correct. We can check the RPKI table for these static entries. We would expect that this would validate prefixes from XRv3 and invalidate them from CSR1. This table typically represents a list of prefixes learned from a server. That is why using extended-communities to distribute RPKI state is valuable from a scalability perspective; there is no new AFI/SAFI or negotiated capabilities for RPKI specifically.

```
! XRv1
router bgp 85
  rpki route 1.0.0.0/8 max 20 origin 589837
  rpki route 13.0.0.0/8 max 20 origin 589837
```

```
RP/0/0/CPU0:XRv1#show bgp rpki table ipv4
```

Network	Maxlen	Origin-AS	Server
1.0.0.0/8	20	589837	0.0.0.0
13.0.0.0/8	20	589837	0.0.0.0

We see that the path from CSR1 was invalid because the originating AS is 65537 (1.1) and not 589837 (9.13) like we configured. This is the first time we have seen “valid” or “invalid” states for eBGP prefixes as they would normally be “not-found”.

```
RP/0/0/CPU0:XRv1#show bgp ipv4 unicast 1.12.0.0/16
[snip]
Not advertised to any peer
589837 65537
  10.1.3.13 from 10.1.3.13 (13.13.13.13)
    Origin incomplete, localpref 100, valid, external, group-best
    Received Path ID 0, Local Path ID 0, version 0
    Origin-AS validity: invalid
[snip]
```

Alternatively, the paths from XRv3 are now marked as valid.

```
RP/0/0/CPU0:XRv1#show bgp ipv4 unicast 13.12.0.0/16
[snip]
589837
  10.1.3.13 from 10.1.3.13 (13.13.13.13)
    Origin incomplete, metric 0, localpref 100, valid, external, best,
group-best
    Received Path ID 0, Local Path ID 1, version 226
    Origin-AS validity: valid
```

A quick verification on CSR7 shows that this validity was properly signaled throughout the iBGP network. The invalid path on XRv1 was not even considered for best-path, so everyone else will see this network as not-found from other ASBRs that advertised it. Adjusting the RPKI validity of a route can be used to manipulate the BGP best-path selection process if other attributes cannot be used, although this is highly undesirable.

```
R7#show bgp ipv4 unicast 13.12.0.0/16 bestpath
BGP routing table entry for 13.12.0.0/16, version 270
Paths: (2 available, best #2, table default)
  Not advertised to any peer
  Refresh Epoch 11
  589837
    11.11.11.11 (metric 30) from 2.2.2.2 (2.2.2.2)
      Origin incomplete, metric 0, localpref 100, valid, internal, best
      Extended Community: 0x4300:0:0
      Originator: 11.11.11.11, Cluster list: 2.2.2.2
      path 7F8D84CAF6D8 RPKI State valid
      rx pathid: 0, tx pathid: 0x0
```
